The pathogenesis of this disease is discussed in detail in Chapter 44. The primary defect is in the protective processes that maintain the integrity of the gastric mucosal barrier. Although some gastric acid secretion is required for the development of stress gastritis, it is clear that the hypersecretion of acid is not the cause of mucosal injury. Altered gastric mucosal blood flow and impaired clearance of hydrogen ions from the mucosa appear to be of particular importance. Stress gastritis should be differentiated from the deep, often solitary ulcerations occurring in patients with severe central nervous system lesions (Cushing ulcers). Generally, hemorrhage is the only symptom that patients with stress gastritis experience. Overt bleeding is often heralded by the appearance of flecks of blood in the gastric aspirate. The superficial nature of the lesions makes perforation unlikely.

Prophylactic therapy is directed toward preventing hemorrhage, primarily by neutralizing gastric acid, augmenting mucosal defenses, and removing or preventing physiologic stress. Antacids, H₂-receptor antagonists, and sucralfate have all been used successfully to prevent stress gastritis. Alkalinization of the gastric contents is associated with oral and fecal flora colonization of the stomach and has raised concerns about an increased risk of nosocomial pneumonia. This concern has prompted the use of sucralfate as a preferred prophylactic agent instead of antacids or cimetidine.¹²⁰ However, a prospective, randomized trial of 1,200 critically ill patients receiving either ranitidine or sucralfate for stress ulcer prophylaxis found that those patients receiving ranitidine had a lower bleeding rate (1.7%) than the sucralfate group (3.8%). There was no difference in mortality or incidence of ventilator-assisted pneumonia.¹²¹

The success of these prophylactic measures has led to a dearth of recent experience in managing patients bleeding from stress gastritis. Based on early reports, attention to blood replacement, intravascular volume restoration, and correction of coagulation defects are associated with the cessation of hemorrhage in nearly 80% of cases and as such are the principal means of initial treatment. A variety of nonoperative techniques have been employed with variable success in arresting hemorrhage from stress gastritis including endoscopic and embolization techniques and the selective catheterization of the left gastric artery with continuous infusion of vasopressin.¹²²

Based on these same early experiences, very few patients bleeding from erosive gastritis require operative intervention to arrest hemorrhage. A variety of surgical treatment options have been reported including vagotomy and pyloroplasty with oversewing of bleeding sites, vagotomy and hemigastrectomy, total gastrectomy, and gastric devascularization. The dilemma facing the surgeon is that these critically ill patients poorly tolerate extensive procedures, yet lesser operations often fail to control hemorrhage. Regardless of the operation performed, mortality risk depends on the underlying illness, particularly in the presence of multiple organ failure. Mortality rates between 30% and 60% are commonly quoted, with as many as one fourth of the deaths resulting from continued hemorrhage. Rebleeding rates ranging from 25% to 61% have been reported. The combination of vagotomy, hemigastrectomy, and oversewing of bleeding points has been touted as more

successful in these patients; however, rebleeding rates of 11% to 44% and operative mortality rates ranging from 33% to 63% have been associated with this procedure.¹²³ More extensive operations, such as near-total gastrectomy or total gastrectomy, are associated with significant mortality, although they successfully stop hemorrhage.

Gastroesophageal Varices

Cirrhosis is a leading cause of death in the United States and variceal hemorrhage is a common mode of death for these patients. About 30% of people with cirrhosis develop gastroesophageal varices, and of these individuals, about 30% bleed as a result, usually within 1 to 2 years of diagnosis. Gastroesophageal varices are a significant cause of UGI hemorrhage, accounting for about 20% of such cases. Patients with bleeding gastroesophageal varices tend to have much higher rebleeding rates, transfusion requirements, lengths of hospitalization, and risk of death than do patients bleeding from nonvariceal causes.^{113,124,125}

Although the basic tenets of resuscitation for massive variceal hemorrhage are similar to those for any cause of massive bleeding, intravenous volume resuscitation should be particularly judicious. The hyperaldosteronemic state of cirrhosis promotes sodium and water retention with aggravation of ascites and peripheral edema. Accurate blood replacement is imperative since overtransfusion may worsen portal hypertension and exacerbate hemorrhage. Invasive cardiac monitoring with Swan-Ganz catheterization may be particularly useful for guiding volume replacement. Coagulation deficits should be aggressively corrected by administering fresh frozen plasma. Thrombocytopenia, secondary to hypersplenism or dilution, should be treated promptly with pooled platelet transfusions. Sedatives are best avoided or used sparingly because cirrhosis impairs the liver's ability to metabolize many of these drugs. Adequate prophylaxis for delirium tremens should be administered to alcoholics.

As with other sources of upper GI hemorrhage, early endoscopy is imperative for successful diagnosis and therapy. The identification of varices alone is not adequate to incriminate them as the source of the hemorrhage since up to half of patients with cirrhosis bleed from a source other than varices. Furthermore, endoscopy may identify factors associated with a heightened risk of variceal hemorrhage such as the size and number of varices and the presence of red, blue, or other colored spots on the varix. The presence of gastric and duodenal varices and portal hypertensive changes in the gastric mucosa (portal gastropathy) will influence therapeutic decisions and prognosis.

Although vasopressin has commonly been used in the management of variceal hemorrhage, recent reports suggest the superiority of somatostatin or its synthetic analogue, octreotide. It is thought that octreotide causes splanchnic arteriolar vasoconstriction and reduces variceal and azygous vein flow with limited direct effects on portal pressure.¹²⁶ Meta-analyses have shown that the infusion of somatostatin is more effective and safer than vasopressin in the pharmacologic control of variceal hemorrhage.^{127,128} Other studies have shown that somatostatin or octreotide can improve the results of sclerotherapy or endoscopic variceal ligation.¹²⁹⁻¹³¹ In addition to the enhanced efficacy in controlling hemorrhage, the use of octreotide eliminates the cardiac risks of vasopressin infusion (i.e., coronary artery vasoconstriction, myocardial ischemia, and infarction). Although neither somatostatin nor vasopressin plus nitroglycerin definitively treats the bleeding esophageal varices, these modalities may provide initial control of hemorrhage, reducing transfusion requirements and providing time for resuscitation before definitive treatment.

Another temporizing method used for massively bleeding patients is balloon tamponade using a Sengstaken-Blakemore

tube or a Minnesota tube. These devices consist of a gastric tube with esophageal and gastric balloons. In the case of a Minnesota tube, a proximal esophageal lumen allows for the aspiration of swallowed secretions. Inflation of the gastric (and, if required, esophageal) balloons tamponade the bleeding varices, controlling hemorrhage in more than 80% of cases. Hemorrhage recurs in 25% to 50% of patients upon deflation of the balloons, thus limiting this technique to a temporizing role.¹³² The greatest value of these tubes is for arresting massive hemorrhage that has been unresponsive to other measures, allowing time for resuscitation and angiographic definition of the portal system before definitive treatment.

When used inappropriately, these tubes can be associated with significant morbidity and mortality. Complications occur in 4% to 9% of patients, with the most frequent being aspiration pneumonitis. Measures to prevent pulmonary complications include endotracheal intubation before tube insertion and the placement of an esophageal tube to remove swallowed salivary secretions. Other significant complications include esophageal rupture or necrosis and airway occlusion during the attempted removal of an incompletely deflated gastric balloon.

Endoscopic sclerotherapy, endoscopic clipping, and endoscopic variceal ligation (banding) have become the most widely used modalities for the initial definitive control of bleeding esophageal varices. Several studies have confirmed that these techniques arrest acute variceal hemorrhage in 90% to 95% of patients. In general, a patient bleeding from esophageal varices should undergo urgent sclerotherapy or banding of the varices at the time of the first emergency endoscopy. A single treatment controls variceal bleeding in more than 70% of patients, and a second treatment increases the rate of control to 90% to 95%. Continued or recurrent hemorrhage after endoscopic treatment requires temporary control with balloon tamponade and somatostatin, usually followed by emergency portal decompression either with transjugular intrahepatic portosystemic shunting (TIPS) or with surgery.^{133,134} Following an initial episode of variceal hemorrhage, several options are available for the prevention of further hemorrhage. These options and the operative management of bleeding esophageal varices is discussed in detail in Chapter 58.

Mallory-Weiss Tears

The Mallory-Weiss syndrome is acute UGI hemorrhage that occurs after retching or vomiting due to a mucosal tear in the gastric cardia. Mallory and Weiss postulated that violent emesis against an unrelaxed cardia was the mechanism of injury. They were able to produce similar mucosal tears in cadavers by forcing gastric contents against an occluded gastroesophageal junction.¹³⁵ The typical patient who develops the syndrome is an alcoholic who begins to retch and vomit after an alcohol binge, although this syndrome may also be found in nonalcoholics with bouts of emesis. Initially, the vomitus consists of gastric contents without blood and subsequently the patient develops hematemesis and/or melena. Overall, these lesions occur in 5% to 10% of patients who present with upper GI bleeding.^{113,124,125}

The initial management of these patients is similar to that of patients bleeding from other sources of upper GI hemorrhage and includes volume resuscitation, gastric lavage, and decompression. Most patients with Mallory-Weiss tears stop bleeding spontaneously, either before treatment or after these early measures. Once bleeding has stopped, rebleeding is rare.

In patients who continue to bleed despite these maneuvers, nonoperative and operative therapeutic options are available. Nonoperative management, consisting of endoscopic electrocoagulation, banding, or injection therapy, has been successfully applied to these lesions.¹³⁶ In cases not amenable to endoscopic therapy, operative management consists of oversewing the laceration through an anterior longitudinal gastrotomy in the middle third of the stomach.

LOWER GASTROINTESTINAL HEMORRHAGE

Although the passage of maroon or bright red blood per rectum may occur in the presence of a massive upper GI hemorrhage, this finding most commonly indicates a source distal to the ligament of Treitz. The absence of blood in bilious nasogastric lavage fluid further supports a distal location of hemorrhage. Although numerous potential causes of lower GI hemorrhage are possible (see Table 65.2), colonic diverticulosis and colitis are by far the most common. Small-bowel sources and other colonic pathology such as colon cancer are relatively unusual causes of acute GI hemorrhage.

Diagnostic Approach

9 The most important question to answer when presented with a patient with lower GI hemorrhage is not, "What is bleeding?" but rather, "Where is the bleeding?" The common causes of colonic hemorrhage are mucosal in nature, not palpable, and not visible from the serosal surface of the bowel. Therefore, it is imperative that the surgeon make every effort to localize the source of bleeding preoperatively since it is usually impossible to locate the bleeding source intraoperatively. Tagged RBC scanning and/or angiography should be obtained as early as possible after presentation.

After determination that the source is likely from a lower GI source, it is important to first exclude anorectal causes of hemorrhage, such as hemorrhoidal bleeding, by inspection and anoscopy. The authors' approach is then to obtain a tagged RBC scan as soon as practical, or in occasional cases of massive hemorrhage, to proceed directly to angiography. If the tagged RBC scan localizes a bleeding site, then one may continue supportive care to determine if bleeding will stop spontaneously as it will in the majority of cases. If bleeding continues, then the patient may proceed to either surgical excision of the bleeding site or angiography with embolization. If the tagged RBC scan does not demonstrate bleeding, then it is probable that bleeding has stopped. One may then proceed to colonoscopy after adequate mechanical bowel preparation. In the authors' experience, colonoscopy in an actively bleeding patient with an unprepped colon is seldom satisfactory. If the bleeding is rapid enough to warrant emergency surgery, bleeding can usually be demonstrated by one of these modalities. It should be the very rare patient who will need to proceed to surgery for lower GI hemorrhage with failed preoperative localization. In these cases a careful search for small-bowel bleeding sources, possibly including intraoperative small-bowel endoscopy, should be performed. If this still does not demonstrate a source and the blood appears confined to the colon, a total abdominal colectomy should be performed. However, the surgeon should be aware of a significant failure rate even after this radical surgery.

Colonic Diverticulosis

In Western society, the prevalence of colonic diverticula increases with age such that about 60% of people in their seventh decade of life are affected and the incidence increases roughly 1% per year. Only about 20% of patients with diverticulosis have symptoms attributable to these lesions and less than 5% experience hemorrhage.¹³⁷ Hemorrhage from diverticular disease is most often massive, associated with hematochezia and varying degrees of hemorrhagic shock. Classically, patients present with a sudden occurrence of mild lower abdominal discomfort, rectal urgency, and the subsequent passage of a large maroon or melanic stool. Because the colon can

contain large volumes of blood, neither the volume nor the frequency of bloody stools is a reliable guide to the rate of hemorrhage. Despite the massive nature of hemorrhage, most patients with diverticular disease stop bleeding spontaneously. In one series, 76% of patients initially stopped bleeding spontaneously, though 38% of these rebled. Of those who rebled, less than one fourth required surgery.¹³⁸

Bleeding associated with diverticular disease comes from a perforated vasa recta located at the neck or apex of a diverticulum. The vasa recta penetrates the colonic wall from the serosa to the submucosa through obliquely oriented connective tissue septa. Protrusion of colonic mucosa through this connective tissue plane causes apposition of the diverticulum and the vasa recta (Fig. 65.4). Ulceration of the mucosa within the neck of the diverticulum and disruption of the arterial wall produces hemorrhage into the lumen of the bowel. Although diverticular disease is more prevalent in the left colon, right-sided lesions account for half or more episodes of bleeding.^{138,139}

The massive nature of the bleeding caused by colonic diverticula limits the diagnostic usefulness of colonoscopy. Rarely is a bleeding vessel seen within a diverticulum, and the presence of blood or clot within a diverticulum is of no diagnostic benefit. Selective mesenteric arteriography may demonstrate the luminal extravasation of contrast; however, in one study of patients bleeding from diverticulosis, angiographic localization was effective in less than 20% of patients.¹⁴⁰ Failure to visualize a bleeding point is usually due to cessation of active bleeding at the time of angiography.

Given the relatively low risk of recurrent hemorrhage, patients who stop bleeding should be treated expectantly. About 10% of patients bleeding from colonic diverticula continue to bleed and ultimately require operative intervention. Embolization of bleeding vessels in the colon has been reported to be safe and effective in the majority of patients; however, there is a definite risk of ischemic complications.¹⁴¹⁻¹⁴⁴ The rapid nature of the hemorrhage and the difficulty in defining the site of bleeding through the endoscope have largely thwarted endoscopic attempts at control of diverticular hemorrhage.

FIGURE 65.4. Colonoscopic view of a colonic diverticulum. A vasa rectum is seen entering the diverticulum and forming one of the walls.

Patients who continue to bleed from diverticular disease should undergo resection of the colon segment that contains the site of bleeding. Even after successful localization of a bleeding source, the least extensive operation that can usually be contemplated is a hemicolectomy or wide segmental colectomy. Tagged red blood cell scanning, while sensitive, cannot pinpoint a bleeding site with great accuracy. Although angiography usually gives more precise localization, correlation between the vascular pattern and the anatomic location is sufficiently imprecise to warrant at least a segmental resection. Lastly, measurement with colonoscopy is notoriously misleading, with even experienced endoscopists making erroneous estimations about the precise site of a lesion.

Although a subtotal colectomy for nonlocalized ongoing colonic hemorrhage may occasionally be necessary, it should be performed only after exhaustive attempts to localize the site of bleeding. Subtotal colectomy is associated with greater perioperative morbidity rates than segmental resection and postoperative diarrhea may present a significant problem to elderly patients. However, if the patient continues to bleed massively from the colon and all attempts at preoperative and intraoperative localization are unsuccessful, subtotal colectomy with ileoproctostomy may be required.

Colonic Angiodysplasia

Sometimes called vascular ectasias or arteriovenous malformations, these lesions are believed to arise from the age-related degeneration of previously normal intestinal submucosal veins and overlying mucosal capillaries. Angiodysplasia is located most frequently in the cecum and ascending colon, although it may be found more distally in 20% to 30% of cases. Multiple lesions may be present in as many as 40% to 75% of cases.¹⁴⁵ Microscopically, angiodysplasia consists of dilated, thin-walled vessels that appear to be ectatic veins and venules localized within the submucosa. A dilated submucosal vein is often found and occasionally an enlarged artery. Angiodysplasia is generally thought to be an acquired lesion associated with aging, but the exact etiology is unknown.

The prevalence of colonic angiodysplasia in the general population appears to be less than 1%.¹⁴⁶ These lesions may present with hematochezia, melena, occult blood loss, or iron deficiency anemia. Bleeding lesions are most commonly found in the right colon. As compared to diverticular bleeding, episodes of hemorrhage from vascular ectasias are usually less severe and are somewhat more likely to recur. After the initial episode of hemorrhage, the majority of patients will stop bleeding spontaneously.¹⁴⁷

Vascular ectasias may be diagnosed by either colonoscopy or by selective mesenteric angiography. Colonoscopy has been reported to have a sensitivity of 80% in demonstrating vascular ectasias.¹⁴⁸ However, colonoscopic diagnosis of these lesions in actively bleeding patients may be confounded by the presence of other incidental lesions including traumatic and suction artifacts produced during the examination. In addition, after significant bleeding and hypovolemia, the shunting of blood flow away from the intestinal mucosa may obscure these lesions in inadequately resuscitated patients. Colonoscopy can be used effectively to treat vascular ectasias, either by coagulation or possibly injection of sclerosants.^{149,150}

Selective mesenteric angiography may also demonstrate these lesions and complement colonoscopy, particularly in patients who are massively bleeding or in whom colonoscopy was unrevealing or incomplete. Characteristic angiographic findings include a densely opacified and slowly emptying, dilated, tortuous vein (found in 90% of patients); a vascular tuft (seen in 66% to 75% of patients); and an early-filling vein (usually a segmental vein in the cecum or right colon, although at times, it may be the ileocolic vein).

The natural history of these lesions was revealed by the clinical course of 101 patients with colonic vascular ectasias.¹⁴⁸ Of the 15 asymptomatic individuals without a history of bleeding, none bled during a period of follow-up to 68 months (mean, 23 months). For 31 patients with overt bleeding or anemia who were treated only with blood transfusion, the rebleeding rate at 1 and 3 years was 26% and 46%, respectively. This study suggests that the risk of bleeding for incidentally discovered lesions is minimal, whereas the risk of recurrent hemorrhage for most symptomatic patients is substantial and may increase with time.

Medical treatment of vascular ectasias has been used, although there is currently no proven effective medical therapy. Hormone treatment using high-dose estrogens and progesterone has been used since the 1950s, but convincing proof of efficacy is lacking. Indeed, most evidence would suggest no antibleeding effect of hormonal treatment.¹⁵¹ More recently, the antiangiogenic drug thalidomide has been suggested as a treatment option.^{152,153}

Patients bleeding from colonic vascular ectasias can be treated endoscopically. Nonrandomized investigations with vascular ectasias managed with monopolar electrocoagulation, endoscopic injection sclerotherapy, contact probes, and lasers have been published with good results. All methods appear to be effective for treating bleeding vascular ectasias and all are associated with procedure-related morbidity rates of 2% to 10%. Perforation has been reported in all of these experiences with rates of 2% to 3%.

Patients bleeding from vascular ectasias in whom endoscopic hemostatic methods are unsuccessful or unavailable can be treated with resection of the colon following preoperative localization of the bleeding site. For the usual patient bleeding from a vascular ectasia in the cecum or ascending colon, a right colectomy with ileotransverse colostomy is the treatment of choice. The value of preoperative localization of the bleeding site cannot be overstated, and every effort should be made to determine the site of hemorrhage prior to laparotomy.

Ischemic Colitis

Ischemic colitis is a common cause of lower gastrointestinal hemorrhage, especially in the elderly. Bleeding is a common presenting manifestation of ischemic colitis, occurring in approximately one half to three fourths of patients, but it is usually not massive.^{154,155} Although ischemic colitis may occur with occlusion of a major artery (such as ligation of the inferior mesenteric artery during abdominal aortic aneurysm repair), in most cases it results from impaired local microvascular perfusion of the colonic wall. It occurs most commonly in the elderly, who often have significant medical comorbidities. Renal failure requiring hemodialysis, hypertension, cardiovascular disease, vasoactive medications, and a variety of other risk factors have been associated with the disease.¹⁵⁶ In many cases a specific initiating event cannot be identified. Any segment of the colon may be involved. Profound ischemia may lead to full-thickness necrosis, peritonitis, and perforation. Lesser degrees of ischemia may result in vague abdominal pain, diarrhea, and mild to moderate bleeding. Life-threatening hemorrhage is uncommon.

Ischemic colitis can be diagnosed with colonoscopy, in which case the mucosa may vary from edematous to hemorrhagic and necrotic in appearance. Angiography is usually not helpful in these cases, as it rarely demonstrates major vessel occlusion.¹⁵⁵ Most patients will recover uneventfully with supportive care alone. When operative management is required, it is often necessitated by peritonitis or other signs of full-thickness necrosis. In these critically ill patients the mortality rate is relatively high due to the critical nature of these patients' preexisting comorbid conditions.

UNUSUAL CAUSES OF ACUTE GASTROINTESTINAL HEMORRHAGE

As outlined in Tables 65.1 and 65.2, a wide variety of other pathologic processes may present with acute GI hemorrhage. Although these lesions generally comprise a relatively small percentage of the total number of cases of overt GI hemorrhage, they can present vexing problems to the clinician faced with a bleeding patient in whom the usual etiologies have been excluded. There are a number of case reports in the literature of extremely rare causes of GI bleeding that will not be discussed here. The following lesions occur commonly enough that a clinician is likely to encounter them in his or her practice.

Dieulafoy Vascular Malformation

Dieulafoy vascular malformation is an unusual cause of recurrent hematemesis, in which bleeding originates from an unusually large (1- to 3-mm-diameter) artery running through the gastric submucosa for variable distances. Erosion of the gastric mucosa overlying the vessel results in necrosis of the arterial wall and brisk hemorrhage. The size of the mucosal defect is usually small (2 to 5 mm) and without evidence of chronic inflammation. These lesions may rarely occur in other anatomic locations such as the colon.¹⁵⁷⁻¹⁵⁹

Painless hematemesis and melena are typical. Recurrent bleeding with spontaneous cessation is also common. In a collective review of 101 cases, the mean age of the patients was 52 years, and the lesion occurred twice as frequently in men as women. There was no significant association with alcohol abuse or antecedent symptoms.¹⁶⁰

The diagnosis is most frequently made endoscopically by demonstrating arterial bleeding from a pinpoint mucosal defect. Occasionally, a small arterial vessel may be seen protruding from the gastric mucosa. Characteristically, the lesions are located within 6 cm of the esophagogastric junction along the lesser curvature, although they may occur in other sites as well.

Most patients can be managed endoscopically by injection of epinephrine, sclerotherapy, banding, clipping, or coagulation.¹⁶¹⁻¹⁶³ A subset of patients will require retreatment or surgical excision for control of hemorrhage. After cessation of hemorrhage, few patients rebleed from these lesions, even when treated only by endoscopic methods.¹⁶⁴

Gastric Antral Vascular Ectasia

Sometimes abbreviated as GAVE syndrome, this entity is also known as “watermelon stomach” because of its characteristic endoscopic appearance. Longitudinal erosions are seen in the antrum radiating from the pylorus. It usually causes chronic blood loss and not acute hemorrhage. The etiology is not known, but there is a prominent association with connective tissue disorders. It can usually be treated by endoscopic argon coagulation but occasionally antrectomy is necessary.¹⁶⁵

Angiodysplasia of the Stomach and Small Intestine

Angiodysplastic lesions may occur throughout the GI tract. Similar to colonic lesions, they appear as minute, flat, or slightly raised red lesions with round or stellate shapes. The margins are characteristically sharp with a pale mucosal halo surrounding the lesion. The lesions are frequently multiple and are found most commonly in the stomach and duodenum,

although esophageal and small-intestinal involvement has also been described.

In general, these lesions may be diagnosed by endoscopy, although their minute size and sessile nature may complicate their detection. The lesions may be readily mistaken for submucosal hemorrhage associated with acute gastritis or trauma artifact from a nasogastric tube or the endoscope. These lesions may be demonstrated arteriographically since they have many of the features described for colonic vascular ectasia.

Endoscopic injection of sclerosants, electrocoagulation, and laser photocoagulation have all been used to treat gastroduodenal angiodysplasia with good results. The multiplicity of lesions often necessitates several courses of therapy to eliminate recurring hemorrhage. Surgical resection of the gastric or intestinal wall containing the lesion and oversewing of the bleeding lesion have been reported to successfully control hemorrhage.

Aortoenteric Fistula

Although communication between the aorta and the intestine may occur as a result of aneurysmal disease or infectious aortitis (*primary aortoenteric fistula*), most of those encountered currently are due to the erosion of an aortic vascular prosthesis through the wall of the distal duodenum (*secondary aortoenteric fistula*). The incidence of aortoenteric fistula following aortic reconstructive surgery is about 1%, with most of these fistulas arising from the proximal graft anastomosis. Secondary aortoenteric fistulas are believed to develop after prolonged contact of a prosthetic graft with a fixed segment of intestine. Ultimately, erosion of the graft through the bowel wall results in a low-grade infection around the graft; involvement of the infection with the suture line leads to dehiscence of the anastomosis and massive hemorrhage.

The interval between aortic reconstructive surgery and the onset of GI hemorrhage may range from a few days to many years; the median interval is about 3 years.¹⁶⁶ Most patients have an initial episode of GI bleeding (i.e., herald bleed) that is followed in hours, days, or weeks by catastrophic hemorrhage. Patients may also complain of back or abdominal pain and less commonly have fever or signs of sepsis from infection of the graft.

The diagnosis of an aortoenteric fistula must be considered in any patient with an aortic prosthesis or an abdominal aortic aneurysm who presents with GI hemorrhage. Endoscopy should be urgently performed following resuscitation to disclose evidence of an aortoenteric fistula or another cause of bleeding (e.g., peptic ulcer disease with stigmata of recent hemorrhage). If endoscopy fails to demonstrate an aortoenteric fistula or another convincing source of bleeding and the patient is not massively bleeding, computed tomography may be helpful in detecting perigraft infection or other evidence of an aortoenteric fistula. In patients who are actively bleeding, exploratory laparotomy with exposure of the proximal graft should be undertaken. Identification of an aortoenteric fistula or erosion requires resection of the graft with extra-anatomic bypass and repair of the duodenal wall. The operative management of aortoduodenal fistulas is considered in greater detail in Chapter 88.

Meckel Diverticulum

Bleeding from a Meckel diverticulum is a common cause of lower GI hemorrhage in children but is rare in older adults. Meckel diverticula are present in approximately 2% of the population. The lifetime risk of a complication from a Meckel diverticulum is about 4%.¹⁶⁷ About 25% of patients with symptomatic Meckel diverticula present with hemorrhage.¹⁶⁸

In a series of 17 patients who bled from Meckel diverticula, 11 experienced frank hemorrhage, while six had chronic occult blood loss. The incidence of GI hemorrhage is greatest in the first decade of life and steadily decreases from that point. In one series, no patient older than 40 years of age, and only one patient older than 31 years, bled from a Meckel diverticulum,¹⁶⁸ although it has been reported in the very elderly.¹⁶⁹ The pathogenesis of this bleeding involves the occurrence of ectopic gastric mucosa with peptic ulceration of adjacent bowel wall. Although these lesions may be demonstrated by enteroclysis, abdominal scintigraphy following the intravenous injection of ⁹⁹technetium-pertechnetate demonstrates the ectopic gastric mucosa within the diverticulum, suggesting the correct diagnosis. Treatment consists of resecting the diverticulum with a cuff of adjacent bowel. Diverticulectomy alone will be associated with persistence of the ulcer and the possibility of recurrent hemorrhage.

Small-Intestinal Diverticulum

Diverticular disease of the small intestine is another uncommon cause of either upper GI hemorrhage (duodenal) or lower GI hemorrhage (jejunoileal diverticula).¹⁷⁰ The pathogenesis is similar to that of colonic diverticula with erosion of a vasa recta through the diverticular wall and the acute onset of massive hemorrhage. Depending on the location of the diverticulum, patients may present with either hematemesis, melena, or hematochezia. Hemorrhage from this source can be a vexing diagnostic problem because jejunoileal lesions are beyond the reach of the gastroscop and bleeding from duodenal diverticula may be difficult to discern. Mesenteric angiography or intraoperative enteroscopy may localize the site of hemorrhage in actively bleeding patients. Segmental resection of the involved intestine is the treatment of choice.

Hemorrhage Following Endoscopic Procedures

Significant hemorrhage can occur following endoscopic biopsy, sphincterotomy, and other traumatic procedures. Fortunately, these complications are uncommon. Colonoscopy may rarely cause clinically significant bleeding (0.1% to 0.2%).¹⁷¹ Biopsy of lesions increases the risk up to 10-fold. Usually this is minor and self-limited and may occur up to 12 days after the procedure.¹⁷² The bleeding site can be confirmed by tagged red cell scanning, arteriography, or colonoscopy. Arteriography and colonoscopy can be used therapeutically as described previously. Endoscopically placed bands such as those used for esophageal varices have also been reported to be successful in arresting hemorrhage.⁹⁰ Surgical treatment is rarely required.

Hemorrhage following endoscopic biliary sphincterotomy occurs in approximately 2% of patients.^{173–175} Mild immediate bleeding is common and is usually self-limited. Late hemorrhage usually occurs within 48 hours of the procedure but can occur many days after sphincterotomy.¹⁷⁶ More severe hemorrhage can usually be controlled by epinephrine injection,^{176,177} making the need for operative treatment uncommon.

CHAPTER 66 ■ ULCERATIVE COLITIS

EMILY FINLAYSON

KEY POINTS

- 1 Ulcerative colitis is a disease largely limited to the mucosa and submucosa of the colorectum. This process is continuous, beginning at the rectum, and extending proximally for variable distances.
- 2 The acute indications for surgical intervention are bleeding, fulminant disease, and toxic megacolon. Failure of medical management, dysplasia, and cancer are indications for elective surgery.
- 3 The intestinal manifestations of ulcerative colitis are cured by removal of the colon and rectum.
- 4 Current surgical options include proctocolectomy with end ileostomy and proctocolectomy with ileal pouch–anal anastomosis.
- 5 Although operative and late complications after ileal pouch–anal reconstruction are not uncommon, patient satisfaction and quality-of-life scores after surgery are high.

Ulcerative colitis is an idiopathic inflammatory bowel disease (IBD) that affects the mucosa of the colon and rectum. The disease presents with equal frequency in males and females, with onset predominantly in the second to fourth decades. Diarrhea and gastrointestinal bleeding are the hallmark clinical features. Medical treatment temporarily improves symptoms and allows periods of remission. However, 10% to 35% of patients with chronic ulcerative colitis will eventually require surgical intervention for medically refractory symptoms or complications of the disease.^{1,2}

EPIDEMIOLOGY

In North America, the incidence of ulcerative colitis is approximately 2.2 to 14.3 cases per 100,000 person-years.^{3–6} Rates of disease are highest in northern Europe, the United Kingdom, and North America. The incidence of disease appears to be rising in Asia, Africa, and South America.⁷ Although ulcerative colitis typically begins in the teen years or early adulthood, a second and perhaps a third peak of incidence are noted. Secondary peaks of disease activity occur in the 40- to 60-year age range, with a smaller third peak after the age of 70 years. Some studies reveal gender-related differences in late-onset disease, with men more likely than women to be diagnosed later in life.⁸

Etiology and Risk Factors for Ulcerative Colitis

Despite more than five decades of investigation, the underlying biologic mechanisms of the disease process are poorly understood. Many risk factors have been examined without conclusive results. Although diet, oral contraceptive use, breast-feeding, measles infection/vaccination, and other infections have all been implicated, the evidence connecting these factors to ulcerative colitis is weak. Other risk factors, however, have been shown more convincingly to have an association with the disease.

Cigarette Smoking. For more than 20 years, a decreased incidence of ulcerative colitis has been noted in individuals who smoke.⁹ In 1989, meta-analytical studies revealed that smokers were 40% as likely as nonsmokers to develop ulcerative colitis.¹⁰ In addition, primary sclerosing cholangitis and pouchitis are both decreased in those who smoke, suggesting a systemic protective effect.^{11,12} The mechanisms underlying this protective effect are unclear. Former smokers also appear to be at increased risk of developing ulcerative colitis.¹³ Smoking has been associated with a less severe disease course of ulcerative colitis. Active smokers are half as likely to be hospitalized as nonsmokers. Former smokers are 50% more likely to be hospitalized and twice as likely as current smokers or those

who have never smoked to require colectomy.¹⁴ One French study revealed that patients with ulcerative colitis who ceased smoking had more active disease, more hospitalizations, and greater need for immunosuppressants than those who continued to smoke.¹⁵

Appendectomy. Large meta-analyses reveal a protective effect of nearly 70% of appendectomy for the development of ulcerative colitis.¹⁶ Population-based studies in the Netherlands, Sweden,¹⁷ and Denmark^{18,19} have documented varying rates of development of chronic ulcerative colitis among patients who have undergone appendectomy. In the Dutch study, the cohorts were followed for 5 million person-years and observed for a subsequent diagnosis of ulcerative colitis. Patients who had undergone appendectomy had only three-quarters the incidence of ulcerative colitis compared with controls. The Danish study, however, revealed only a 13% decreased likelihood for the development of ulcerative colitis.

Like smoking, appendectomy may also influence the course of ulcerative colitis. Results from two studies from Japan and Australia suggest this possibility. In the Japanese study, patients who developed ulcerative colitis after appendectomy were less likely to develop recurrent symptoms than colitis patients with an intact appendix.²⁰ In the Australian study, ulcerative colitis patients who had undergone appendectomy prior to the diagnosis were significantly less likely to subsequently require colectomy.²¹

Genetics. Inflammatory bowel disease has been shown to cluster within families, implicating genetics in determining susceptibility. Twin studies reveal a concordance rate of 10% in monozygotic twins and 3% in dizygotic twins.²² Population-based studies report that 5% to 10% of those affected have a positive family history.²³ Population-based studies have demonstrated a 10-fold increased risk for developing ulcerative colitis among relatives of patients with the disease.²⁴

Genome-wide scans have been used to type genetic markers in families containing more than one member with ulcerative colitis and to identify shared chromosomal regions. These genetic linkage studies have revealed that the IBD2 locus (12q13) may be associated with ulcerative colitis. Unfortunately, several important genes in this region, including the $\beta 7$ integrin family and signal transducer and activator of transcription 6, have not been found to correlate with this disease.²⁵ The most intensively studied region has been the chromosome 6 region (IBD3), especially regions associated with major histocompatibility complex class II genes. Meta-analysis combining results from 29 studies reveal positive associations to DR2, DR9, and DRB1*0103.²⁶

Although there is mounting evidence that genetic factors play a role in the development of ulcerative colitis, their major role is likely one of making the individual genetically susceptible to other inciting events. Recent evidence suggests that IBD results when the interaction of gut microorganisms, the host epithelium, and the host immune system create an environment of dysregulated immunity.²⁷ The molecular pathways of these interactions, however, are still debated.

PATHOLOGY

Macroscopic Appearance

- 1 Ulcerative colitis is a disease largely limited to the mucosa and submucosa of the colon and rectum. The rectum is nearly always involved, and the disease generally presents in a continuous fashion from this point proximally. The proximal extent of disease and the severity vary. When the entire colon is involved, termed *pancolitis*, a phenomenon called *backwash ileitis* may occur, characterized by a dilated, mildly

FIGURE 66.1. Pseudopolyps (colonoscopic photo). (Courtesy of Peter Higgins, MD, University of Michigan, Ann Arbor, MI.)

inflamed terminal ileum. The typical presentation may be less clear if a patient develops toxic megacolon initially. In this case, the colon may be diffusely thickened, gangrenous, and perforated. The resultant full-thickness disease may appear similar to Crohn colitis, both macroscopically and microscopically.

Gross inspection of the colon reveals confluence of numerous ulcers with areas of heaped up, regenerating mucosa, called *pseudopolyps* (Fig. 66.1). This process is continuous, beginning at the rectum, and extending proximally for variable distances. Superficial fissures, consisting of linear coalescence of ulcerating lesions, are seen. In contrast to Crohn disease, ulcerative colitis is not transmural, and therefore tends to lack features of thickening and fibrosis. The loss of the mucosa eventually leads to the loss of the normally visualized endoscopic vascular pattern (Fig. 66.2).

Microscopic Appearance

Early in the inflammatory process, the disease involves acute inflammatory cells, predominantly neutrophils, infiltrating into the crypts of Lieberkühn at the base of the mucosa to form crypt abscesses (Fig. 66.3). As the process continues, crypt abscesses coalesce, and superficial desquamation of overlying epithelium leads to the formation of ulcers. Cryptitis undermines the adjacent mucosa, which becomes edematous. If this inflammation is severe, the muscularis propria may undergo myocytolysis, resulting in hyperemia and wall thinning during severe attacks. Granulation tissue is formed as the ulcerated areas heal, which extends to, but rarely through, the submucosa.

CLINICAL FEATURES/COURSE

Ulcerative colitis is typically characterized by bloody diarrhea. The majority of patients present with a mild attack of predominantly distal disease (80%), while a minority of patients (20%) develop pancolitis.²⁸ In 10% to 20% of patients, an initial attack will rapidly progress to fulminant colitis, characterized by frequent, bloody bowel movements; fever; and abdominal tenderness.

The signs and symptoms correlate with the severity, duration, and location of disease. Patients with proctitis most often present with urgency, frequency, tenesmus, and bloody, mucoid diarrhea. The abdominal examination is usually unremarkable. On proctoscopy, the rectal mucosa appears inflamed and friable.

FIGURE 66.2. A: Loss of normal vascular pattern (colonoscopic photo). B: Contact bleeding. C: Granularity. D: Ulceration and friability. E: Colonic stricture. (Reproduced with permission from Corman ML. *Colon and Rectal Surgery*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

In patients with pancolitis, anemia, fatigue, and anorexia may be present. These patients may exhibit weight loss due to decreased oral intake during attacks, increased metabolism, and protein loss during chronic or recurrent episodes. Patients with chronic colitis have loss of mucosal folds and haustra.

FIGURE 66.3. Histograph of crypt abscess. (Courtesy of Henry Appelman, University of Michigan, Ann Arbor, MI.)

The walls of the colon undergo fibrosis and shortening, leading to a “lead pipe” appearance on contrast radiography (Fig. 66.4). With the loss of functional mucosa, the colon may be unable to absorb fluid, leading to diarrhea.

Extraintestinal manifestations involve dermatologic, ocular, articular, and hepatic tissues (Table 66.1). These manifestations complicate 25% to 30% of cases.²⁹ With treatment, dermatologic and ocular manifestations may resolve. Unfortunately, hepatic and articular manifestations do not resolve, and primary sclerosing cholangitis may require liver transplantation for management.

Of dermatologic manifestations, erythema nodosum and pyoderma gangrenosum are the most common. Erythema nodosum, found in approximately 9% of patients with ulcerative colitis,³⁰ is a rash consisting of tender, symmetric, raised erythematous papules, predominantly found on the extensor surfaces of the arms and legs (Fig. 66.5A). Skin disease commonly parallels the activity, but not the severity or extent of bowel disease. Occasionally, the appearance of erythema nodosum precedes the diagnosis of IBD. The uncommon condition of pyoderma gangrenosum is associated with IBD in 50% of cases.³¹ Pyoderma gangrenosum begins as an erythematous plaque, papule, or bleb, usually in the pretibial region, but may progress to an ulcerated, necrotizing, tender wound with ill-defined, purple-red margins (Fig. 66.5B). In both diseases, treatment of the underlying bowel disease process is key to management.

FIGURE 66.4. Lead-pipe colon radiograph. (Reproduced with permission from Corman ML. *Colon and Rectal Surgery*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005, color plate.)

The ocular manifestations of ulcerative colitis are commonly episcleritis, and less commonly, but more seriously, iritis and uveitis. Episcleritis is characterized by the development of eye redness without visual disturbance, whereas scleritis and iritis/uveitis may be associated with blindness if left untreated. Episcleritis is associated with pain or tenderness to palpation, but is not associated with loss of vision, photophobia, or loss of a normal pupillary response to light. Episcleritis may be confused with conjunctivitis; however, the latter is not associated with discomfort. Scleritis is a more severe ocular disorder, which may result in impaired vision. Scleritis differs

from episcleritis in that with episcleritis the sclera remain white, as opposed to pink in scleritis. Scleritis may lead to retinal detachment or optic nerve swelling.³² Uveitis and iritis are often associated with joint and skin extraintestinal manifestations. The inflammation includes the iris, ciliary body, and, posteriorly, the vitreous, choroids, or retina. These complications are characterized by the acute onset of painful eyes, blurred vision, and headache, and may herald the diagnosis of ulcerative colitis. Slit-lamp examination establishes the diagnosis. Treatment of uveitis typically involves cycloplegics and topical steroids, but may require systemic steroids and immunosuppression.

The musculoskeletal manifestations of ulcerative colitis are the most common extraintestinal complications.³³ The arthritic

FIGURE 66.5. A: Erythema nodosum. B: Pyoderma gangrenosum. (A reproduced with permission from Goodheart HP. *A Photoguide of Common Skin Disorders: Diagnosis and Management*. Baltimore, MD: Lippincott Williams & Wilkins; 1999.)

component is believed to be associated with loss of intestinal integrity associated with colitis, and the release of bacteria, lipopolysaccharide, and cytokines. A generalized inflammatory response is manifested as arthritic discomfort. Acute synovitis may occur in up to 20% of patients, reported as sudden joint pain with effusion and tenderness, usually associated with increased disease activity.³³ Medical therapy targeted at improving mucosal integrity or altering bacterial flora relieves symptoms.

Ankylosing spondylitis occurs in a small percentage of patients with ulcerative colitis (3% to 5%), with the highest-risk patients possessing the human leukocyte antigen (HLA) B27 haplotype.³³ Unfortunately, sacroiliitis/spondylitis does not bear a relationship to clinically active bowel disease and thus may progress unnoticed. On examination, these patients have tenderness of the sacroiliac joint and loss of truncal motion and, later, will have decreased chest expansion with cervical fusion. In longstanding disease, pain may dissipate as the spinal ligaments or joints ossify. Neither medical nor surgical therapy has an effect on these manifestations, and thus treatment is geared toward slowing disability and minimizing deformity.

Asymptomatic abnormalities of hepatic enzymes are the most common manifestation of hepatobiliary disturbances in ulcerative colitis. At least 50% of patients have fatty infiltration of the liver, with cirrhosis present in 3% to 5%.³⁴ Although fatty liver may reverse with treatment of primary disease, cirrhosis will not.

The most severe extraintestinal manifestation of ulcerative colitis is primary sclerosing cholangitis (PSC). This chronic cholestatic syndrome is characterized by fibrosing obliteration of the bile ducts. Best diagnosed by endoscopic retrograde cholangiopancreatography or magnetic resonance cholangiopancreatography, primary sclerosing cholangitis demonstrates beadlike extrahepatic and intrahepatic bile ducts. Epidemiologic studies have shown that nearly 70% of patients with primary sclerosing cholangitis have ulcerative colitis, whereas the incidence of primary sclerosing cholangitis in patients with ulcerative colitis is only 2% to 7%.^{35,36} In patients with ulcerative colitis, the relative risk of development of cholangiocarcinoma also is 31 times greater than in PSC patients without ulcerative colitis.³⁷ In general, primary sclerosing cholangitis is a chronic, progressive disease with the rate of progression being variable. Current medical treatment involves the use of ursodeoxycholic acid and endoscopic dilation of the bile duct strictures until liver failure necessitates transplantation. Currently, the only known curative treatment for primary sclerosing cholangitis is orthotopic liver transplantation. Whether the addition of immunosuppression to maintain the transplanted organ ameliorates colitic symptoms and affects the advent of colonic malignant degeneration is not clear.^{38,39}

DIAGNOSIS

The diagnosis of ulcerative colitis requires a combination of history and endoscopic/radiologic findings. Diarrhea, often with blood or mucus, is a dominant symptom. Urgency of bowel movements may be disabling, with tenesmus due to an inflamed rectum. If the disease is more severe, associated systemic symptoms, including fever, arthritis, skin manifestations, and weight loss, may ensue. On a chronic basis, the disease causes fatigue and malaise.

At first presentation, the disease must be differentiated from infectious causes. Stool cultures should be obtained to rule out common infectious colonic pathogens, such as *Campylobacter*, *Salmonella*, *Shigella*, pathogenic *Escherichia coli*, *Clostridium difficile*, *Giardia*, and cytomegalovirus.

Colonoscopy with ileal intubation or flexible sigmoidoscopy should be the next invasive test. Biopsies of abnormal and quiescent areas are of key importance, with the locations

of the biopsies carefully documented. Because the rectum is involved in 90% to 95% of cases with ulcerative colitis, flexible sigmoidoscopy may establish the initial diagnosis. In early cases, findings include a granular texture, resembling small bowel, and mucosal friability. With moderately active disease, spontaneous hemorrhage occurs, whereas in severe cases, the mucosa is ulcerated with copious bleeding and a purulent exudate. Over time, the mucosa regenerates, with multiple areas of raised granulation tissue and mucosa (pseudopolyps).

Examination at initial presentation of accompanying symptoms and histologic examination of biopsies may help to differentiate ulcerative colitis from Crohn disease (Table 66.2). Distinguishing features include the clinical presentation, which for Crohn disease may include cramping abdominal pain, suggestive of small-bowel involvement. At colonoscopy, the presence of discontinuous disease or “skip areas” suggests Crohn disease, and, if possible, ileal intubation with biopsies should be performed. Edema of the interhastral septa with thickening and blunting suggests ulcerative colitis. In both diseases, grossly normal-appearing mucosa should also be biopsied, as histopathologic abnormalities are frequently present that may assist in establishing the diagnosis. If severe acute inflammation exists, a limited flexible sigmoidoscopy may be all that is necessary to initiate treatment, as a more aggressive examination may result in colonic perforation.

Radiologic examination is helpful to determine the extent of disease and to distinguish ulcerative colitis from Crohn disease. In patients presenting with fulminant colitis, a dilated transverse colon, with a diameter of 5 to 7 cm, is often visible on plain film. Mild cases of ulcerative colitis may be seen on air contrast barium enema with spiculation and collar button ulcers. When contrast studies are used to visualize longstanding ulcerative colitis, the loss of haustra with a flat mucosa and narrowed caliber (lead-pipe colon; see Fig. 66.4) may be seen. Additionally, in Crohn disease, the small bowel is often involved and should be investigated with a small bowel follow-through, video-capsule endoscopy, or computed tomography enterography.

Expression of antibodies may help differentiate the two disease processes. The expression of perinuclear antineutrophil cytoplasmic antibodies versus antibodies to the cell wall of mannan polysaccharide (anti-*Saccharomyces cerevisiae* antibodies [ASCAs]) segregates the diseases in that antineutrophil cytoplasmic antibodies correlate with ulcerative colitis, whereas ASCA is a marker for Crohn disease. Unfortunately, neither antibody is sensitive enough to serve as a sole screening test because up to 64% of patients with Crohn disease have ASCAs.⁴⁰ Nevertheless, these antibodies are part of the Prometheus IBD First Step panel, which helps to determine whether a patient may have IBD and which type of disease may be present.

The presentation of ulcerative colitis and Crohn disease may overlap sufficiently in the initial presentation that discrimination between the two entities is not possible. In the 8% to 10% of cases in which this occurs, the colitis is labeled “indeterminate.” Because the natural history and surgical management of these two diseases is different, diagnosis is paramount. Prior to restorative proctocolectomy, every attempt should be made to exclude the diagnosis of Crohn disease. Several studies, however, have found similar functional results among patients with ulcerative colitis and those with indeterminate colitis after ileal pouch–anal anastomosis.⁴¹

MEDICAL MANAGEMENT

Aminosalicylic Acid Compounds

Aminosalicylates are the primary medical treatment modality for mild to moderate ulcerative colitis, used to both induce remission and prevent relapse. Sulfasalazine, composed of

TABLE 66.2**DIAGNOSIS****CLINICOPATHOLOGIC FEATURES OF ULCERATIVE COLITIS VERSUS CROHN DISEASE**

■ MANIFESTATION	■ ULCERATIVE COLITIS	■ CROHN DISEASE
Transmural inflammation	Seldom	Common

Mucosal friability	Common	Uncommon
Vascular pattern	Absent	Normal
Fat wrapping	Rare	Common

5-aminosalicylic acid (ASA) linked to sulfapyridine by a diazo-bond, was the first compound in this family to be identified. The active component is 5-ASA, and formulations have been created to release the active moiety at different pH levels. Mesalamine (Asacol) is released at pH greater than 7; for Pentasa, controlled release begins in the duodenum. Rowasa is released at pH greater than 6, thus facilitating distal ileal and colonic exposure. The former is most effective in treating patients with proximal small bowel disease, whereas Rowasa is the preferred medication for ileocolonic disease. Rowasa may be delivered as suppositories or enemas to treat distal colonic disease. Colonic bacteria contain azo-reductase enzymes that are able to split sulfasalazine to liberate 5-ASA in the colon, where it is believed to act topically.

Steroids

Corticosteroids continue to play a major role in the induction of remission in patients with moderate to severe ulcerative colitis or for patients who have failed aminosalicylate treatment. The use of corticosteroids is designed to control symptoms and achieve remission, not to maintain long-term remission. Steroid therapy is followed by a taper to minimize the medical complications of long-term steroid use. In severe cases, prednisone, 40 to 60 mg/d, is used to induce remission. If a hospitalized patient exhibits acute worsening of symptoms (e.g., escalating bloody diarrhea), intravenous steroids, in a dose equivalent to 300 mg of hydrocortisone or 60 mg of methylprednisolone, should be administered.

Budesonide is often effective and has the advantage of producing fewer systemic effects. Budesonide is believed to have greater potency due to high affinity for the glucocorticoid receptor and low systemic bioavailability due to extensive first-pass hepatic metabolism.⁴² Budesonide capsules delay the release of the active component until the ileum and ascending colon, where the pH is greater than 5.5.

Immunomodulators

The purine antimetabolites, azathioprine and its metabolite, 6-mercaptopurine, may also be used to achieve steroid-sparing remission. These agents are used to facilitate a remission induced by cyclosporine. These agents act via inhibition of purine biosynthesis, nucleotide interconversions, DNA and RNA synthesis, and chromosomal replication.⁴³ A prolonged interval of 3 to 6 months may be necessary for these agents to demonstrate their full suppressive potential. Approximately 60% of patients achieve long-term remission with these agents.⁴⁴ Measurement of the activity of thiopurine methyltransferase, as well as 6-thioguanine levels, allows for dose adjustment. Toxicities induced by this family of drugs include bone marrow suppression, especially leukopenia, which is dose dependent. Additionally, liver toxicity and allergic reactions, manifested as a combination of fever, rash, myalgias, or arthralgias, may limit utilization. Pancreatitis occurs as another manifestation of hypersensitivity in 2% of patients.⁴⁵

Cyclosporine therapy for refractory colitis is effective in 40% of patients who have failed steroids alone.^{46,47} Cyclosporine is a lipophilic peptide with inhibitory effects on both the cellular and humoral immune systems. Cyclosporine down-regulates the cellular immune response by blocking the production of interleukin (IL)-2 by T-helper lymphocytes. Molecularly, cyclosporine binds to cyclophilin, and this complex binds to and inhibits calcineurin, a cytoplasmic phosphatase enzyme involved in the activation of T cells.⁴⁸ Cyclosporine also indirectly inhibits B-cell function by interfering with the production of activation factors and interferon- γ by T-helper cells.⁴⁹

The dose of cyclosporine recommended to induce remission is 4 mg/kg per day. Patients with hypocholesterolemia, hypokalemia, or hypomagnesemia must have a reduced dose of 2 mg/kg to avoid the risk of seizures. Long-term therapy is avoided because of the associated side effects of hypertension, renal insufficiency, paresthesias, and seizures. After

induction of remission with cyclosporine, patients may be transitioned to either salicylates or to an antimetabolite, such as azathioprine, or 6-mercaptopurine. However, long-term follow-up in these patients fails to demonstrate a decreased incidence of colectomy, with 60% to 80% of these patients requiring operation within 1 year.⁵⁰ This delay, however, may allow an elective operation instead of an emergency procedure.

Another calcineurin inhibitor, tacrolimus, a member of the macrolide antibiotic family, may be useful adjunctive therapy for steroid-refractory ulcerative colitis. Tacrolimus has improved absorption compared to cyclosporine. The fact that tacrolimus is a member of the macrolide antibiotic family accounts for its additional promotility effect.⁵¹

Biologic Agents

Anti-Tumor Necrosis Factor. Recently, anti-tumor necrosis factor (TNF) therapy (infliximab) has been approved for treatment of severe, refractory ulcerative colitis. In a large, multicenter randomized trial, patients with moderate to severe ulcerative colitis who received infliximab therapy were more likely than controls to be in clinical remission at 54 weeks (45% vs. 20%).⁵² There appears to be no significant difference in response rates between patients who received 5-mg/kg and 10-mg/kg dosing regimens.

Treatment Algorithms. With many effective agents available to treat ulcerative colitis, there are several options for induction and maintenance of remission. Treatment strategy algorithms have been developed by consensus panels based on up-to-date information on medical therapies⁵³ (Algorithm 66.1). Patients with mild ulcerative colitis generally begin therapy with oral aminosalicylates. Progression to moderate disease is generally treated with a steroid taper. Patients who become steroid dependent should be started on biologic or immunomodulator therapy. Options for patients unresponsive to steroid therapy and with severe disease include treatment with cyclosporine, infliximab, or surgical resection.

TABLE 66.3 INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR URGENT SURGERY IN ULCERATIVE COLITIS

Acute severe colitis (70%)
Toxic colonic dilatation (20%)
Perforation (<10%)
Hemorrhage (<5%)

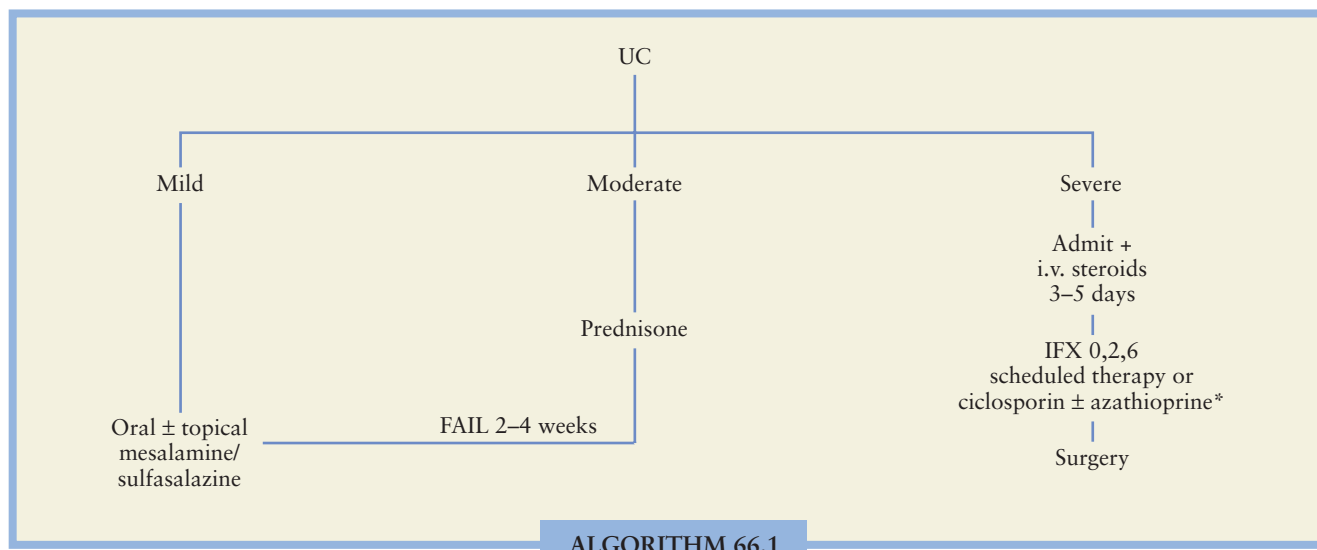

Adapted from Nicholls RJ. Review article: ulcerative colitis—surgical indications and treatment. *Aliment Pharmacol Ther* 2002;16(suppl 4):25–28.

INDICATIONS FOR SURGICAL INTERVENTION

- 2 The acute indications for surgical intervention are fulminant disease, toxic megacolon, and hemorrhage (Table 66.3). Failure of medical management, dysplasia, and cancer are indications for elective surgery.

Surgical Emergencies

Acute, severe (fulminant) colitis is the most common indication for acute surgical intervention. Severe colitis is defined as the passage of more than six bloody stools per day with a temperature higher than 37.5°C, tachycardia, hemoglobin less than 75% of normal, and an increased sedimentation rate. Affected patients are hospitalized, resuscitated, and placed on intravenous steroids. Fulminant or severe colitis may be precipitated by superimposed infectious colitis and the latter diagnosis should be ruled out in all patients presenting with severe colitis. Fever, defecation more than 8 to 10 times per 24-hour period, frequent bloody movements, hypoalbuminemia, and abdominal tenderness are findings concerning for failure of

ALGORITHM 66.1

ALGORITHM 66.1. Treatment paradigm for remission induction in ulcerative colitis. (Reproduced with permission from Panaccione R, Rutgeers P, Sandborn WJ, et al. Review article: treatment algorithms to maximize remission and minimize corticosteroid dependence in patients with inflammatory bowel disease. *Aliment Pharmacol Ther* 2008;28:647–688.)

medical management. Barium enema, narcotics, anticholinergic drugs, and antidiarrheal agents should be avoided because these agents may precipitate toxic megacolon. Patients who show no signs of improvement in the first 48 to 96 hours or have an incomplete response after 7 days of medical treatment are likely to fail medical therapy.⁵⁴

Toxic megacolon is the most feared presentation of ulcerative colitis and is characterized by severe systemic signs of illness—fever, abdominal pain and tenderness, tachycardia, leukocytosis—and dilation of the colon (greater than 6 cm transverse colon on abdominal radiograph). Perforation may be present without radiologic evidence in 25% of patients. With either toxic megacolon or severe colitis, perforation is a possible sequela that has historically been associated with a high mortality rate. Recent advances in medical and surgical intervention, however, have decreased mortality rates to less than 3%.⁵⁵

Hemorrhage is an unusual indication for surgery in ulcerative colitis. Most often, bleeding is controlled with medical treatment of the disease. Even with distal disease, total abdominal colectomy is often sufficient to arrest hemorrhage as the fecal stream is diverted. Rectal stump bleeding can be controlled with systemic or topical steroids. In severe cases, hemostasis can be achieved with intrarectal tamponade with epinephrine-soaked gauze. Proctectomy should be a last resort as it complicates later surgical reconstruction.

Emergency Procedures for Ulcerative Colitis. Total abdominal colectomy with end ileostomy is the most common and safest procedure for patients who require emergency intervention for ulcerative colitis. This procedure is rapid, removes the greatest source of the patient's symptoms, and allows withdrawal of steroids postoperatively. The rectum is preserved to minimize the extent of surgery in a systemically ill patient and to facilitate future pelvic procedures (i.e., the creation of a pelvic reservoir). However, this approach may mandate a second procedure (completion proctectomy or pouch formation) and perhaps a third procedure (ileostomy closure). Formerly, blowhole colostomy and ileostomy had been advocated for management of toxic megacolon, in which a dilated, edematous, thin-walled colon might lead to intraoperative spillage with subsequent septic complications. With improved medical management and earlier surgical intervention, fewer patients have advanced disease and perforation at the time of surgery, and therefore this procedure is rarely used.

There are several strategies for securing the rectal stump after subtotal colectomy to prevent “rectal stump blowout.” The rectal stump may be managed by either suturing or stapling the proximal end. If the stump is very friable, it may be left with enough sigmoid to create a mucous fistula to the anterior abdominal wall. If the end will not reach the skin, it may be brought through the fascia and sutured in the subcutaneous space. A third option is to place a large catheter intra-anally to stent the sphincters open, facilitating dependent drainage.

Elective Surgery for Ulcerative Colitis

The most common indication for elective proctocolectomy is intractability. These patients often have longstanding colitis and have failed aggressive outpatient medical regimens with significant side effects due to medications.

While biopsy-proven cancer is an absolute indication for proctocolectomy, management of dysplasia is more controversial. In patients with high-grade dysplasia or a dysplasia-associated lesion or mass (DALM), the risk of synchronous cancer is over 40% and surgical resection is warranted.⁵⁶ Management of low-grade dysplasia is not as straightforward. Small prospective studies have found a wide range of rates of progression to high-grade dysplasia or cancer, with some studies failing to document an increased risk for cancer.^{57,58} A

meta-analysis, however, that included over 500 patients found a ninefold increase in the risk of developing cancer.⁵⁹ One potential source of confusion is in the histologic diagnosis of dysplasia. Even among experts, there is interobserver variability as high as 60% in the classification of dysplasia.⁶⁰

Cancer prophylaxis is sometimes a motive for elective colectomy. Most investigators believe that oncogenesis is related to the severity and duration of disease. Although the risk is low during the first 8 to 10 years of ulcerative colitis, cancer incidence increases at a rate of 1% to 2% per year following this interval.^{61–63} Malignancy may be present in up to 18% of patients with an intact colon having sustained 30 years of disease,⁶⁴ and reflects an increase in relative risk of 2.6- to 5.4-fold relative to the general population. Cancers develop in the flat mucosa, not in inflammatory regions. Surveillance colonoscopy is essential. Notably, at the first colonoscopy for surveillance, approximately 10% of patients will already have dysplasia,⁵⁶ with a rate of 3% for the development of dysplasia at subsequent follow-up colonoscopy if the first colonoscopy is unrevealing.⁶⁵ Current recommendations for surveillance colonoscopy include a minimum of 18 biopsies to have a 95% sensitivity to detect any type of dysplasia, and most studies recommend four biopsies from at least nine sites, with at least four sites in the rectosigmoid.⁶⁶

Procedure Options for Elective Surgery. The advantages, disadvantages, indications, and contraindications for elective surgical options for ulcerative colitis are summarized in Table 66.4.

4 Total Proctocolectomy with End Ileostomy. For years, total proctocolectomy with end ileostomy was the operative “gold standard” for ulcerative colitis. This procedure is one of the earliest for ulcerative colitis, and is still considered the standard against which other procedures must be compared. This operation has several advantages. With removal of the entire colon and rectum, cancer risk is eliminated. With an end ileostomy, patients do not experience the urgency and frequency associated with ileoanal pouch. It remains the operation of choice for patients with sphincter dysfunction. An intersphincteric perineal dissection results in a smaller perineal wound than that traditionally created for an abdominoperineal dissection and results in better wound healing rates. Stoma-related complications such as hernia, stenosis, and skin excoriation, however, are not uncommon.

Colectomy with Ileorectal Anastomosis. In this procedure, the entire abdominal colon is removed, and the ileum is anastomosed to the rectum at approximately the level of the sacral promontory. The postoperative leak rate is very low, around 2%,⁶⁷ and the procedure is technically easy to perform with either a hand-sewn or stapled anastomosis. The procedure spares the anus. Bowel movements are more numerous and looser than before the operation, but with the addition of bulking agents or antidiarrheal agents, the number of movements may be minimized. The morbidity associated with a pelvic dissection is avoided.

Unfortunately, for most patients with ulcerative colitis, this procedure is not an optimal long-term solution because the disease always involves the rectum and the possibility of neoplastic degeneration mandates surveillance. Indeed, the incidence of carcinoma in the rectal stump at 20 years is approximately 5% to 17%.⁶⁸ At least 10% of patients require subsequent proctectomy for refractory proctitis, and another 10% require proctectomy for poor function. This procedure is a compromise for patients with minimal rectal disease who want intermediate-term preservation of parasympathetic nerve function with continence.

Kock Pouch. The Kock pouch is designed to create a reservoir formed from the ileum with a valve that prevents spontaneous

TABLE 66.4

INDICATIONS/CONTRAINDICATIONS

ADVANTAGES/DISADVANTAGES AND INDICATIONS/CONTRAINDICATIONS FOR ELECTIVE SURGICAL OPTIONS FOR ULCERATIVE COLITIS

■ PROCEDURE	■ ADVANTAGE	■ DISADVANTAGE	■ CONTRAINDICATIONS
Total proctocolectomy/ileostomy	Single operation	Permanent ileostomy	
Kock pouch	Continent abdominal reconstruction	Often requires multiple surgical revisions	Crohn disease
Total abdominal colectomy/ileorectal anastomosis	Single operation, preserves native continence	May require subsequent proctectomy for inflammation or cancer	Active proctitis
Total proctocolectomy/ileal pouch–anal anastomosis	Removes nearly all disease with continent reconstruction	Risk of anastomotic leak, cuffitis, pouchitis, frequent bowel movements/leakage; risk of malignant degeneration in pouch and rectal cuff	Crohn disease, incontinence, distal rectal cancer

emptying. A catheter is inserted through the valve into the reservoir, allowing ileal contents to be emptied by the patient. This construction is created so that motivated patients who did not wish to maintain a permanent, spontaneously emptying ileostomy would be able to intubate the pouch. The nipple valve forms the major source for either a successful or an unsuccessful pouch. The pouch is created from two to three limbs of ileum to form a reservoir, whereas the valve is formed by a portion of the efferent limb intussuscepted into the pouch. This procedure is now rarely performed because of the greater than 50% need for revision due to valve failure and incompetence, technical difficulties with intubation, and fistula formation and because of the advent of the restorative proctocolectomy.

Restorative Proctocolectomy. Parks et al.⁶⁹ and Utsonomiya et al.⁷⁰ independently reported the development of a technique that adapted Kock's ileal pouch and, instead of connecting the pouch to the abdominal wall, anastomosed it to the anus. This type of reconstruction avoids a permanent ileostomy, and the route of evacuation is sustained. This technique is now commonly referred to as the ileal pouch–anal anastomosis, restorative proctocolectomy, or pelvic pouch.⁷¹

This procedure has increased in utilization over the past 25 years and is now the most commonly used operation in the elective management of ulcerative colitis.⁷² Contraindications include Crohn disease, fulminant colitis, low rectal neoplasia, and incontinence. Relative contraindications include obesity because a thick mesentery will preclude mobilization of the bowel into the distal pelvis. A patient with an android-shaped pelvis or a tall patient may have a similar limitation in pouch creation.

The restorative proctocolectomy is usually performed in two stages: (a) total or completion proctocolectomy, pouch formation and pouch–anal anastomosis, and diverting loop ileostomy, and (b) closure of loop ileostomy. The procedure may be performed with laparoscopic assistance. The colon and rectum are resected and the distal rectum is divided, leaving a short rectal cuff. The small bowel mesentery is then mobilized, and an estimate that a created pouch will reach into the anastomosis is made by grasping the most dependent portion of the pouch and measuring that it will reach 3 to 6 cm beyond the bony symphysis pubis.

If the pouch does not reach the rectal cuff, a number of maneuvers may increase length. The small-bowel mesentery may be mobilized to the third part of the duodenum. Peritoneal windows may be made over the vessels releasing tension to the apical portion of the pouch. These windows may be repeated on both sides of the mesentery. Transillumination will identify

vascular arcades that must be preserved, but will also identify vessels that may be ligated to increased length. Application of a vessel clamp with either palpation or Doppler confirmation of adequate blood flow prior to ligation is recommended.

Multiple pouch constructions have been described. Although initially the S- and W-pouches were favored for their increased reservoir capacity and longer length, the J-pouch is now the most popular construction, probably due to the ease of construction, fit into the pelvis, reservoir capacity, and easy emptying. The J-pouch is constructed by stapling two 15- to 20-cm limbs of ileum together, via an enterotomy created at the apex of the J-pouch (Fig. 66.6A). To complete the common wall, another firing of the GIA stapler is necessary, with the distal pouch accorioned onto the forks of the stapler. Other constructions include the S-pouch and W-pouch (Fig. 66.6B,C). An ileoanal anastomosis may be performed by double stapling or, following mucosectomy, via a hand-sewn anastomosis. Stapling preserves the anal transition zone, and this preservation seems to enhance function by retaining neorectal sensation and continence.⁷³ However, this approach does retain a small area of rectum that has the potential for the development of neoplasia, and therefore some investigators have favored mucosectomy. To facilitate mucosectomy, the perineal operator uses a retractor to expose the dentate line. Dilute epinephrine is injected submucosally to raise the mucosa and to prevent bleeding. A needle-tip cautery is helpful to precisely excise the mucosa for a length of several centimeters. The pouch is then lowered into the pelvis and pulled down endoanally for a hand-sewn anastomosis with absorbable sutures.

Postoperative Complications

The most common early postoperative complications are small-bowel obstruction and sepsis. Small-bowel obstruction complicates 11% to 26% of ileal pouch procedures.^{74,75} Creation of a loop ileostomy increases this risk significantly.⁷⁶ Analysis of a series of 1,005 patients revealed that 25% of patients had small-bowel obstruction, with two thirds of the patients having the temporary loop ileostomy as the cause.⁷⁷ Of this 25%, 7.5% had early obstructions and 18% had later obstructions. Overall, of the 254 patients with a small-bowel obstruction, 28% required reoperation. The most common site of obstruction was at the ileostomy,⁷⁸ which has led some surgeons to perform the procedure without ileostomy. Others have implemented the use of Septrafilm (Genzyme Corporation, Cambridge, MA; modified sodium hyaluronic acid and

Ileal pouch construction. **A:** An electrocautery is used to create an enterotomy at the apex of the 15-cm loop of terminal ileum. **B:** The forks of an intestinal anastomosing stapler are pressed into the intestinal limbs, and the instrument is fired. **C:** This is repeated once or twice while the limbs are telescoped onto the stapler, until a 15-cm side-to-side anastomosis is completed. **D:** The apical enterotomy is closed with a simple pursestring stitch. **E:** The stapled construction of the J-pouch. (E reproduced with permission from Corman ML. *Colon and Rectal Surgery*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:1418.)

carboxymethylcellulose), which has been found in a randomized prospective trial to decrease adhesions by 50%, although there is no evidence to date that this leads to a reduced incidence of small-bowel obstruction.⁷⁹ Causes of small-bowel obstruction include adhesions, internal hernia, stenosis, and volvulus around the ileostomy. Though many of the patients resolve the obstruction nonoperatively, approximately one quarter require operative intervention.⁸⁰

The second most common early complication is sepsis, either in the form of pelvic abscess or leak. Sepsis complicates 3% to 37% of cases.^{74,77,81–83} As in all bowel anastomoses, the abscess may be a manifestation of a leak. Leakage of the pouch or the pouch–anal anastomosis occurs in 2% to 15% of cases.^{77,84,85} This serious complication may be revealed radiologically, clinically as an abscess, or as a fistula either to another intra-abdominal structure or to the perineum or vagina. The rate of leakage following the ileoanal pouch procedure is higher in patients with ulcerative colitis than in patients with familial adenomatous polyposis.⁸⁴ The most common location for the leak is at the pouch–anal anastomosis. The most commonly cited factor associated with leak is high-dose steroid use in the preoperative period (ingestion of >40 mg of daily prednisone). Some surgeons perform routine pouch procedures without a defunctioning ileostomy in patients who are not on high-dose steroids.⁸⁶

A loop ileostomy does not prevent leakage at the pouch–anal anastomosis, but it may decrease the morbidity associated with the leak. If a leak occurs, it may be adequately managed with diversion and drainage while allowing time for healing. However, the most common cause of eventual pouch excision is an anastomotic leak, usually due to poor long-term functional results. In one series, 58 patients required pouch excision: 39% due to a leak from the ileoanal anastomosis and 12% due to leak from the pouch. Others have reported an association of leak with pouch failure in up to 24% of patients requiring pouch excision.⁸⁷

Fistula is another manifestation of anastomotic leak, which may develop from the pouch or ileoanal anastomosis and extend to another organ, such as the perineum or vagina. Fistula may occur in the early postoperative period, but may also present months or years later. Pouch fistulas occur with a frequency of 2.8% to 12%.^{74,77,78,83,86} Fistulas are complex to manage, and regardless of whether a local or abdominal technique is used, only half of attempted repairs will be successful.⁸⁸ Contributing factors include pouch ischemia, anastomotic leak, vaginal inclusion in the anastomotic suture line, cryptoglandular infection, and Crohn disease. Abscess drainage, prolonged diversion with loop ileostomy, antibiotics, and local therapy may lead to fistula closure. Variable success has been noted with seton placement, fibrin glue instillation, Surgisis plug placement, ileoanal flaps, and vaginal flaps.⁸⁸

Long-term Sequelae

A summary of the long-term sequelae after ileal pouch–anal anastomosis is listed in Table 66.5.

Pouchitis. Pouchitis is a nonspecific inflammation in the pouch associated with increased stool frequency, urgency, incontinence, bleeding, crampy abdominal pain, malaise, and a low-grade fever. This condition is unique to patients with an ileal pouch and is increased in patients who undergo a pouch procedure for inflammatory bowel disease.⁸⁹ Pouchitis occurs in 30% to 50% of these patients.⁹⁰ The cumulative probability of suffering a second episode of pouchitis after an initial attack within 2 years of a restorative proctocolectomy is 64%. After a single episode, however, only 15% experience chronic symptoms.⁹¹ On pouchoscopy, the mucosa is inflamed and friable with ulceration and discharge. Mucosal biopsies with histologic analysis must confirm the diagnosis.

TABLE 66.5

COMPLICATIONS

LATE COMPLICATIONS AFTER ILEAL POUCH–ANAL ANASTOMOSIS

Pouchitis (30%–50%) ⁹¹
Small-bowel obstruction (11%–26%) ^{75,74}
Cuffitis (5%–14%) ^{97,98}
Pouch failure (5%–10%) ^{87,97,101,102}
Fistula (3%–12%) ^{74,77,78,83,86}
Sexual dysfunction—male and female (5%–20%) ^{104,105}
Cancer—cuff or pouch (rare) ^{99,100}

The cause of pouchitis is unknown. In most of those affected, no etiology is documented. Pouchitis may be due to bacterial stasis, with toxins causing ulceration of the mucosa, or due to ischemia, leading to the production of free radicals. The syndrome is associated with pancolitis and extraintestinal manifestations, including primary sclerosing cholangitis. Fortunately, initial treatment with antimicrobial agents, including metronidazole or a fluoroquinolone, leads to remission in the majority of cases. In refractory cases, a 5-ASA compound is added. Newer data suggest that probiotics may be beneficial in preventing pouchitis and in maintaining remission.^{92,93} Chronic or disabling pouchitis leads to pouch excision in up to 12% of those affected.⁹⁴

Anastomotic Stricture. A small degree of narrowing is often present at the ileoanal anastomosis, particularly after a period of fecal diversion, and is not problematic. This occurs in 7% to 15% of cases.^{74,77,95} This narrowing may be associated with disuse and usually resolves with gentle dilation prior to ileostomy closure. In some cases, however, a stricture may be the result of a healed leak, tension, ischemia, fistula formation, or cuffitis. Anastomotic strictures have also been implicated in the development of pouchitis. Persistent anastomotic stricture is an independent predictor of eventual pouch failure.⁹⁶ In severe cases, pouch revision may be necessary as strictures adversely affect pouch emptying.

Cuffitis. After stapled ileal pouch–anal anastomosis, a small remnant of the anal transition zone is left in the rectal cuff. This area is at risk for the development of symptomatic inflammation or “cuffitis.” These patients may present with symptoms similar to those of pouchitis, including diarrhea, abdominal pain, urgency, perianal pain, and bloody movements.⁹⁷ These patients may be treated effectively with topical 5-ASA or steroid suppositories.⁹⁸

Cancer. Reports of cancer in patients having undergone restorative proctocolectomy have been rare. Both the retained cuff of rectum and the pouch are at risk.⁹⁹ The residual rectum has been documented to develop cancer. These cases have occurred in patients in whom a mucosectomy was performed as well as in patients in whom a mucosectomy was not performed.¹⁰⁰ Because it is difficult to eradicate all mucosal cells even with a meticulous dissection, the risk of cancer is not eliminated with mucosectomy. Patients at increased risk are those who had either dysplasia or cancer in the original proctocolectomy specimen. Additionally, patients with primary sclerosing cholangitis are at increased risk for cancer development. Therefore, continued screening of patients, particularly those with prolonged disease duration, dysplasia or cancer in the excised specimen, and primary sclerosing cholangitis, is essential.

Pouch Failure. A pouch failure rate of 5% to 10% has been reported at most high-volume centers. Risk factors for pouch

failure include (a) patient and disease factors—comorbidity, Crohn disease, and prior anal pathology; (b) operative factors—hand-sewn anastomosis, tension on the ileoanal anastomosis, and use of an ileostomy; and (c) postoperative factors—anastomotic separation, pelvic sepsis, and fistula.^{87,97,101,102} Although the development of Crohn disease in the ileoanal pouch has often been implicated in pouch failure, treatment with infliximab can result in acceptable pouch function in up to 67% of patients.¹⁰³

Sexual Dysfunction. Patients undergoing proctectomy are at risk for injury to the parasympathetic nerve trunks. The morbidity from this injury includes difficulty with bladder emptying, and in men, impotence and retrograde ejaculation. These symptoms may be transient or permanent and are reported to occur in 1% to 20% of patients.^{104,105}

Women may also suffer from dyspareunia (7% to 30%) and leakage during intercourse (2%).^{104,105} There is increasing evidence that fertility following restorative proctocolectomy is substantially reduced, likely secondary to pelvic adhesions.¹⁰⁶ A 2006 meta-analysis study found a threefold increase in infertility among women who had undergone ileal pouch–anal anastomosis compared to women with colitis who were managed medically.¹⁰⁶

Quality of Life. Quality of life incorporates physical and functional outcomes as well as psychosocial factors that contribute to the well-being of patients. Most patients who have had an operative procedure to manage their disease have high satisfaction scores. Although pelvic pouch patients may experience operative complications and have imperfect functional results (i.e., frequent bowel movements and seepage of stool), 95% of patients report satisfaction with postoperative outcomes.^{107–110}

CHAPTER 67 ■ COLONIC POLYPS AND POLYPOSIS SYNDROMES

C. RICHARD BOLAND AND ROBERT S. BRESALIER

KEY POINTS

- 1 Colorectal neoplasia develops through multistep carcinogenesis that involves the gradual accumulation of genetic and epigenetic alterations in the genome. This process usually requires the presence of some form of genomic or epigenetic instability, and neoplasms may require several decades to evolve from their earliest stages to fully advanced disease.
- 2 Colorectal carcinoma usually evolves gradually from colorectal adenomas in clinically identifiable stages; removal of adenomas reduces the incidence of colorectal carcinoma.
- 3 Genetic and familial factors play an important role in the genesis of both the sporadic (common) and syndromic forms of colorectal neoplasia, such as familial adenomatous polyposis and Lynch syndrome.
- 4 The genetic basis of familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer (called Lynch syndrome) have been identified, which facilitates the early identification and diagnosis of affected individuals.
- 5 A wide range of clinical heterogeneity is present in the familial colorectal cancer syndromes, and attenuated forms of familial adenomatous polyposis and Lynch syndrome can be subtle and a challenge to the clinician.

COLORECTAL POLYPS

The gastrointestinal tract accounts for more neoplastic disease than any other organ system in the body. In North America, neoplasms of the colon and rectum have attracted the greatest interest because of their relatively high incidence, and because appropriate intervention can dramatically modify the morbidity and mortality associated with them. The adenoma is the most common precursor of colorectal cancer, and early removal of adenomatous polyps can interrupt the natural history of the disease and prevent death.

Colorectal cancers can develop through one of at least three molecular pathways, and each variety appears to have some unique clinical and pathologic features. The adenoma–carcinoma sequence is virtually canonical at this time and describes the common pathway taken by neoplasms that have “chromosomal instability.” It has subsequently been proposed that “serrated” polyps may be precursors of colon cancers with the microsatellite instability (MSI) phenotype. These polyps are a pathologic hybrid, showing features of both hyperplastic and adenomatous polyps. It is becoming increasingly important to understand the clinical behavior of colorectal neoplasms in the context of the genetic and molecular bases of these lesions.

Classification of Colorectal Polyps

The term *polyp* (from the Greek *polypous*, “morbid excrescence”) refers to a macroscopic protrusion of the colonic mucosa into the bowel lumen. This can result from abnormal growth of the mucosa or from a submucosal process that causes the mucosa to protrude into the lumen. Mucosal polyps can be *sessile*, protruding directly from the colonic wall, or *pedunculated*, extending from the mucosa through a fibrovascular stalk.

Mucosal polyps in the colon can be categorized as *neoplastic*, with malignant potential, and *nonneoplastic*, with no malignant potential (Table 67.1). Neoplastic polyps include benign adenomatous polyps that may evolve to carcinoma,

adenomatous polyps that contain foci of intramucosal carcinoma (carcinoma in situ), and adenomatous polyps in which carcinoma has penetrated the muscularis mucosae (invasive carcinoma). A serrated polyp contains adenomatous features admixed with features of a hyperplastic polyp. A serrated polyp appears to originate in a manner unique from typical adenomas, but is also a premalignant lesion. Sometimes a polyp is found in which carcinoma has completely obliterated the adenomatous tissue from which it arose (polypoid carcinoma).

Nonneoplastic mucosal polyps include hyperplastic polyps, juvenile polyps, Peutz-Jeghers hamartomas, and a variety of inflammatory polyps, including those associated with inflammatory bowel disease. Any submucosal lesion can expand to push the mucosa into the bowel lumen and thus appear as a polypoid lesion. Examples include lipomas, leiomyomas, colitis cystica profunda, pneumatosis cystoides intestinalis, lymphoid aggregates, primary or secondary lymphomas, carcinoid tumors, and other metastatic neoplasms.

Neoplastic Mucosal Polyps. Most colorectal cancers arise in preexisting adenomatous polyps. Neoplastic mucosal epithelium evolves through a series of progressive, cumulative molecular and cellular steps that lead to altered proliferation, cellular accumulation, and glandular disarray. In some instances, the polyp also achieves the ability to invade and metastasize through the adenoma-to-carcinoma sequence.

- 1 Several lines of evidence support the assumption that colorectal adenocarcinomas arise from adenomatous polyps. The descriptive epidemiology of colonic adenomas parallels that of carcinomas, but the benign lesions occur earlier. Adenomas are rare in geographic regions with a low prevalence of colon cancer, and the distribution of adenomas in the colon parallels that of carcinomas. Adenomas often occur in anatomic proximity to colon cancers, and cancer risk is proportional to the number of adenomas present synchronously or metachronously in a patient. Cancer is often present in polyps removed endoscopically or surgically, and the risk for cancer is proportional to the degree of dysplasia or atypia in the polyp.

TABLE 67.1 CLASSIFICATION**CLASSIFICATION OF COLORECTAL POLYPS**

MUCOSAL POLYPS
Neoplastic
Benign
Adenomatous polyps
Tubular adenoma
Tubulovillous adenoma
Villous adenoma
Serrated polyp
Malignant
Carcinoma in situ
Invasive carcinoma
Polypoid carcinoma
Nonneoplastic
Hyperplastic polyps
Juvenile polyps
Peutz-Jeghers polyps
Inflammatory polyps
Normal epithelium
SUBMUCOSAL POLYPS
Lipomas
Leiomyomas
Colitis cystica profunda
Pneumatosis cystoides intestinalis
Lymphoid aggregates
Lymphoma (primary or secondary)
Carcinoids
Metastatic neoplasms

Conversely, histologically evident residual adenomatous tissue may be found surrounding carcinomas. Most important, results from several studies indicate that the systematic removal of adenomatous polyps during screening proctosigmoidoscopy or surveillance colonoscopy decreases the risk for the development of colorectal cancers and death from this disease.

Pathogenesis

Molecular Biology. Genetic changes that lead to the development of adenomas (and carcinomas) can be loosely organized into three major classes: alterations in proto-oncogenes, loss of tumor-suppressor gene activity, and abnormalities of genes involved in DNA repair (Fig. 67.1). Several different mechanisms are involved in altering these genes. Typically, oncogenes become overactive by mutation, rearrangement, or amplification. Tumor-suppressor genes become inactivated by mutation or deletion or silenced through promoter methylation. Tumor-suppressor genes require inactivation of both ² copies of alleles, making this process more complex. It is now clear, however, that the development of adenoma and carcinoma is always associated with the progressive accumulation of genetic changes, and this process is termed *multistep carcinogenesis*.¹

In familial adenomatous polyposis (FAP), Lynch syndrome (previously called hereditary nonpolyposis colorectal cancer [HNPCC]), and other familial syndromes, the first genetic alteration is inherited in the germline. Environmental factors are

then required for the additional genetic mutations that lead to malignant transformation. The clinical phenotype for the inherited predispositions to gastrointestinal cancer is initially normal; such individuals might be thought of as having an exceptional susceptibility to environmental stress. The germline mutation provides the first “hit,” which greatly increases the likelihood of neoplasia and the likelihood that the disease will occur at a young age.² FAP and Lynch syndrome account for about 4% of all colorectal cancers, but it is estimated that as many as 30% of colorectal cancers occur in the context of a positive family history.

“Sporadic” polyps and cancers are associated with multiple somatic mutations, all of which are caused by spontaneous decay of DNA, exogenous insults, or are accidents that occur during the replication of DNA. Adenomas and cancers that develop arise through genomic instability, a process that increases the likelihood that epithelial cells will acquire the number of mutations needed to attain a neoplastic state.³ Destabilization of the genome is a prerequisite to carcinogenesis. This most commonly involves chromosomal instability, which is manifested as widespread chromosomal deletions, duplications, and rearrangements that produce aneuploidy. Alternatively, increased rates of mutations, often in tandemly repeated DNA sequences known as *microsatellites* (microsatellite instability) or a form of epigenetic instability called the CpG island methylator phenotype (CIMP), in which genes are inappropriately silenced by promoter methylation,⁴ are mechanisms that can lead to progressive multistep carcinogenesis. Genomic (or epigenetic) instability generates a large number of random alterations, which are largely deleterious, and leads to the demise of the affected cell. However, occasional genetic alterations enhance growth and survival, and the successive accumulation of those changes will eventually facilitate the evolution of the neoplastic cell.

Cellular proto-oncogenes are a group of evolutionarily conserved genes that play a role in signal transduction and the normal regulation of cell growth. They function by being turned on when growth is stimulated and then turned off when sufficient growth has been achieved. Inappropriate activation of these genes, usually through mutation or rearrangement of the promoter sequences, leads to abnormal transmission of growth regulatory signals, which produce excessive cellular proliferation. Mutations of the *K-ras* oncogene, for example, can be found in about half of sporadic colorectal neoplasms, and this accelerates the growth potential of the early adenoma. Only 9% of small adenomas have *K-ras* mutations, whereas 58% of adenomas greater than 1 cm have a mutated *K-ras* gene. *K-ras* mutations are more common in pedunculated than flat adenomas. However, by themselves, *K-ras* mutations are not sufficient either for the neoplastic phenotype or for tumor progression. A combination of altered growth signals is required for an epithelial cell to achieve autonomous growth. The excessive growth then increases the likelihood that additional genetic alterations will occur.

The tumor-suppressor gene *APC* on chromosome 5q is critical to the evolution of the colorectal adenoma. Allelic losses of chromosome 5q occur early during carcinogenesis in the colon, and may be the initial step in the evolution of colorectal neoplasia.⁵ A combination of mutation of one allele and loss of the other allele of *APC* (usually by partial chromosomal deletion or promoter methylation) commonly occurs in colorectal adenomas. *APC* acts as the “gatekeeper” of colonic epithelial proliferation, and inactivation of this gene will lead to net cellular proliferation and initiation of neoplasia in the colon.⁶ The protein produced by the *APC* gene plays a central role in regulating the intracellular concentrations of the transcription factor, β -catenin. β -Catenin is highly expressed in cells at the base of the colonic crypt, where it stimulates proliferation.⁷ As the cell commits to terminal differentiation, the *APC* gene is expressed, which downregulates β -catenin by phosphorylation, targeting it for degradation.

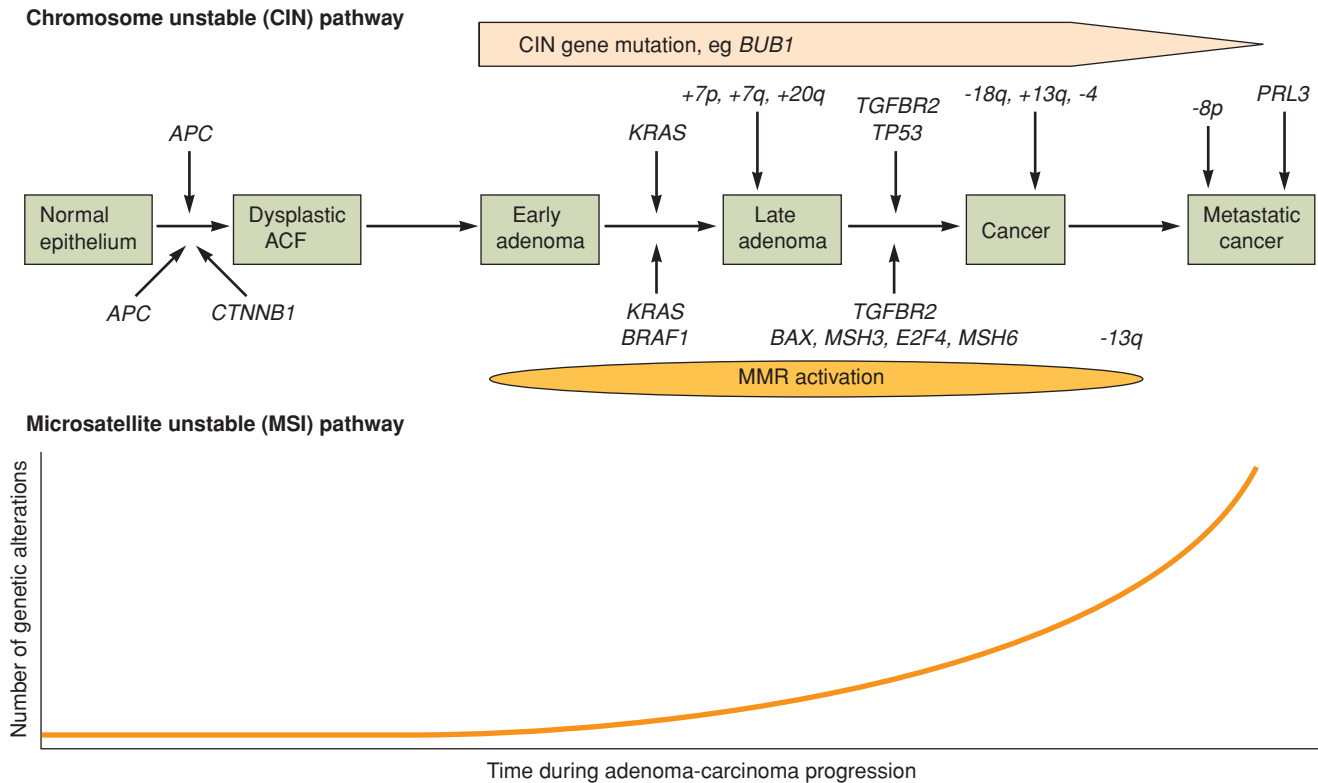

FIGURE 67.1. Proposed sequence of molecular genetic events in the evolution of colon cancer. Carcinomas arise from an accumulation of events whose sequence has been defined for two of the carcinogenesis pathways. As illustrated here, tumors progress through the adenoma-to-carcinoma sequence along pathways marked by chromosomal instability (CIN) or microsatellite instability (MSI). At least one more pathway, characterized by promoter methylation of tumor-suppressor genes, serrated polyps, and cancers with variable degrees of microsatellite instability, is incompletely understood, and not shown here. ACF, aberrant crypt focus; TGF, transforming growth factor. (After Grady WM. Genomic instability and colon cancer. *Cancer Metastasis Rev* 2004;23:11.)

Other genetic changes occur later in the adenoma-to-carcinoma sequence. Stepwise tumor progression is associated, in more than 75% of cases, with loss of one or more tumor-suppressor genes located on chromosome 18q. Several candidate genes are present in this location, and loss of chromosome 18 in the tumor is associated with a poor prognosis. Loss of the *SMAD 4* gene on 18q probably contributes the most to the progressively aggressive nature of neoplasms that advance through the pathway of chromosomal instability. Deletions of chromosome 17p involve the *p53* tumor-suppressor gene, and the *p53* protein normally prevents cells with damaged DNA from progressing from the G1 to the S phase in the cell cycle. Inactivation of the *p53* gene mediates the conversion from adenoma to carcinoma.⁸

Alterations in genes that mediate DNA mismatch repair during replication cause Lynch syndrome, which historically was called HNPCC.⁹ The genes responsible for Lynch syndrome are *MSH2*, *MLH1*, *MSH6*, and *PMS2*. In the hereditary disease, germline mutations inactivate one copy of the gene, and the other allele is inactivated by one of several “somatic” events that occurs locally in an individual colonic epithelial cell. This creates an inability to repair DNA mismatches and results in a diffuse mutational signature in the tumor called microsatellite instability, or MSI. This defect leads to the mutational inactivation of several key genes important for maintaining normal cellular behavior. The transforming growth factor- β receptor II (TGF- β RII), for example, is mutated in 85% of MSI colorectal cancers. This inactivates the receptor, renders the cell unresponsive to TGF- β , and permits it to escape normal growth regulation. The MSI multistep carcinogenesis pathway to tumor development is seen in about 15% of all colorectal cancers,¹⁰ and progression from adenoma to carcinoma occurs

in a shorter time period than occurs the chromosomal instability pathway seen in most colorectal cancers, which is thought to require a period of at least 10 to 20 years. MSI colorectal neoplasms appear to account for two clinical observations. First, the MSI pathway may account for the occurrence of cancers 1 or 2 years after a negative colonoscopic examination. Second, it may account for the relatively small number of adenomatous polyps found with MSI, since they may evolve into cancer in a shorter timeframe than usually occurs.

Histopathology and Malignant Potential

Adenomatous polyps are characterized according to their physical features, size, glandular structure, and degree of dysplasia, which all have important implications for clinical management. Polyps may be sessile, with a broad-based attachment to the colonic wall, or pedunculated, attached to the colonic wall by way of a fibrovascular stalk (Fig. 67.2). Whether a polyp is sessile or pedunculated typically determines whether the endoscopist can remove the polyp completely by snare polypectomy. Diminutive polyps that measure 5 mm or less in diameter are not likely to contain high-grade dysplasia or invasive carcinoma. Malignant potential increases with polyp size in all histologic groups of adenoma.

Adenomas are classified histologically according to their glandular structure. Aberrant (dysplastic) crypts and microadenomas may be the earliest lesions detected in the flat mucosa of patients at risk. These enlarge and progress to macroscopic adenomatous polyps. Tubular adenomas are characterized by a complex network of branching adenomatous glands, whereas villous adenomas contain fronds or folds of mucosa that have

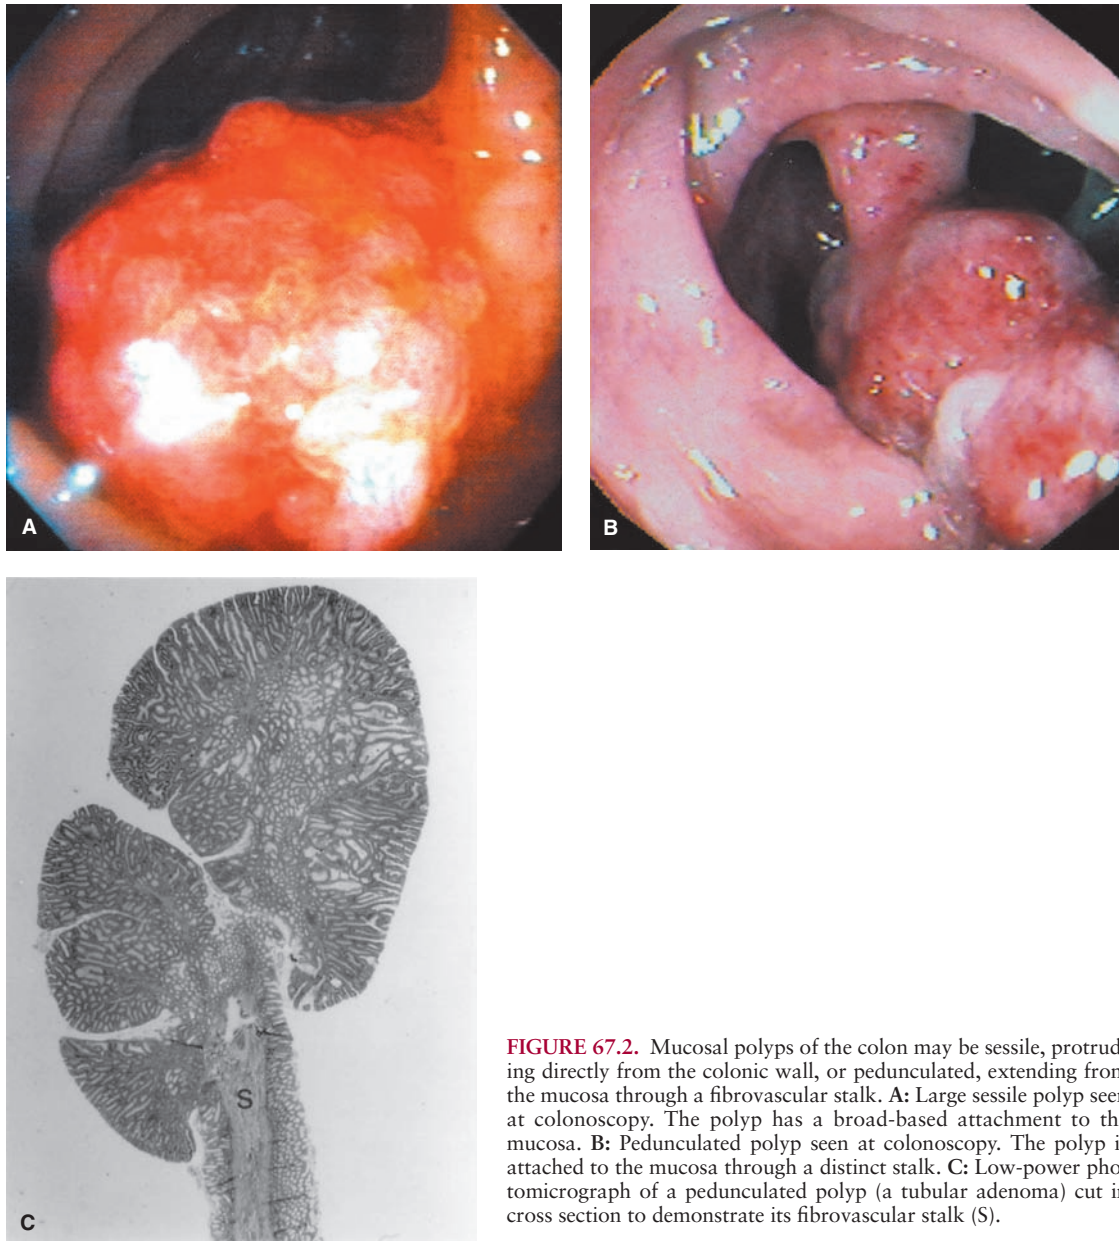

FIGURE 67.2. Mucosal polyps of the colon may be sessile, protruding directly from the colonic wall, or pedunculated, extending from the mucosa through a fibrovascular stalk. **A:** Large sessile polyp seen at colonoscopy. The polyp has a broad-based attachment to the mucosa. **B:** Pedunculated polyp seen at colonoscopy. The polyp is attached to the mucosa through a distinct stalk. **C:** Low-power photomicrograph of a pedunculated polyp (a tubular adenoma) cut in cross section to demonstrate its fibrovascular stalk (S).

overgrown their underlying stroma and project toward the colonic lumen (Fig. 67.3). Often, both histologic types coexist in a mixed tubulovillous adenoma.

All adenomas, by definition, consist of dysplastic mucosa. The term *dysplasia* refers to abnormalities in crypt architecture (such as irregular branching or crowded “back-to-back” glands) and cytologic detail (enlarged, pleomorphic, and hyperchromatic nuclei with multiple mitoses and pseudostratification; Fig. 67.4). Dysplasia may be mild, moderate, or severe, depending on the degree to which these characteristics are present. Severe, or high-grade, dysplasia represents carcinoma in situ when the basement membrane is intact. Extension into the lamina propria denotes intramucosal carcinoma. Invasion into the muscularis mucosae defines invasive carcinoma and the malignant polyp. The degree of dysplasia usually correlates with polyp size and the extent of villous architecture. Occasionally, nonmalignant adenomatous mucosa can be displaced below the muscularis mucosae, probably due to trauma associated with colonic motility.

This must be distinguished from malignant invasion and is termed *pseudoinvasion*.

Even though nearly all adenocarcinomas of the colon and rectum arise in adenomatous polyps, not all polyps evolve into carcinoma; in fact, most do not. The malignant potential of adenomatous polyps is related to polyp size and the histologic characteristics. Large polyps and those with predominantly villous architecture are more likely to contain coincident carcinoma (Fig. 67.5). These features are interdependent, however, because large polyps are more likely to be villous and dysplastic. Adenomas that measure 0.5 cm or less are most often tubular adenomas and rarely contain severe dysplasia or carcinoma (<0.5% in autopsy series). Likewise, only 1% to 2% of adenomatous polyps smaller than 1 cm contain carcinoma, but autopsy studies suggest that as many as 40% of adenomas greater than 2 cm contain cancer. Data derived from the examination of colonoscopic polypectomy specimens indicate similar trends but suggest a lower incidence of cancer-containing polyps.

FIGURE 67.3. Histology of adenomatous polyps. **A:** Tubular adenomas are characterized by a complex network of branching adenomatous glands (see also C). **B:** Villous adenomas consist of glands that extend straight down from the surface to the base as fingerlike projections; this pattern may be suggested by the gross appearance of these polyps. **C:** Tubulovillous adenoma.

Epidemiology

Prevalence. The descriptive epidemiology of adenomatous polyps of the colon and rectum parallels that of colorectal carcinoma with relation to geographic distribution, age, prevalence, and genetic susceptibility. Like colorectal cancer, adenomas are common in Western countries such as the United States, but their prevalence traditionally has been low in parts of Asia, South America, and sub-Saharan Africa. Epidemiologic patterns for

both adenomas and carcinomas are shifting with the acquisition of a “Western” lifestyle in many areas. Estimates of adenoma prevalence in the United States vary depending on the mode of data collection. Data from older studies were collected from autopsies and sometimes grouped all polyps together, whereas more recent studies have examined adenoma prevalence in the context of endoscopic screening. Studies using colonoscopy suggest an adenoma prevalence in patients without symptoms who are older than 50 years that ranges between 20% and 40%.

FIGURE 67.4. Moderate dysplasia. Dysplastic mucosa is characterized by crowded, irregular glands and cells with enlarged, hyperchromatic nuclei of varied size and shape that do not line up uniformly on the basement membrane (pseudopalisading). Adenomas are composed of dysplastic mucosa in which the degree of atypia may vary. These changes precede the development of invasive carcinoma.

FIGURE 67.5. The relation of adenoma size and histology to malignant potential based on an analysis of 7,000 endoscopically removed polyps. The incidence of polyp-associated carcinoma determined from examination of polypectomy specimens is lower than that derived from early autopsy studies. (Data derived from Shinya H, Wolff WJ. Morphology, anatomic distribution, and cancer potential of colonic polyps. *Ann Surg* 1979;1990:675.)

Prevalence rates from autopsy studies are 50% higher. Based on autopsy studies, one half to two thirds of people older than 65 years have colonic adenomas. Adenoma prevalence increases with age in all populations. Age-associated prevalence rates suggest that adenomas precede carcinomas in a given population by at least 5 to 10 years; it may be much longer, as polyps do not produce symptoms and, unlike cancers, dating the onset can only be estimated. Advancing age also correlates with multiplicity of polyps, polyp size, and higher degrees of dysplasia. In addition, 30% to 50% of patients with one adenoma have a synchronous adenoma elsewhere in the colon.¹¹

Heredity. Heredity plays a role not only in FAP and Lynch syndrome but also in the development of sporadic adenomas. Sporadic (nonsyndromic) adenomatous polyps and colon cancers represent more than 95% of colorectal neoplasms. Clinical studies, including case-control and prospective analyses, indicate a two- to threefold increased risk for colon cancer among first-degree relatives of patients with a history of colonic adenoma or carcinoma.¹² The relative risk increases when there are more affected relatives and when adenomas and carcinomas occur in young relatives.¹³ The impact of family history becomes prognostically insignificant in patients whose polyps are discovered after age 60. In most families, it is not possible to separate the impact of commonly shared genes from the impact of shared environmental exposures.

Anatomic Distribution. Autopsy series and colonoscopic examination of patients who do not have symptoms suggest that although adenomas are uniformly distributed throughout the colon, the distribution of clinically important larger adenomas is more similar to that of carcinomas, with a left-sided predominance.

Natural History. Adenomas are common in people older than 50 years, and although most carcinomas arise in adenomatous polyps, relatively few adenomas progress to carcinoma. Little precise information is available on what percentage of adenomas evolve to carcinomas. In Norway, an example of a high-risk Western population, it has been estimated that colorectal adenomas are present in 29% of the population older than 35 years. The conversion rate from adenoma to carcinoma in this group (based on cancer incidence from multiple tumor registries) has been calculated to be 0.25% per year. In other words, the risk that a colorectal cancer will develop in a polyp-bearing person within 10 years is 2.5%. The annual conversion rates to invasive cancer for people with adenomas larger than 1 cm, villous components, and severe dysplasia have been estimated to be 3%, 17%, and 37%, respectively, based on these inferences. Data from a national colonoscopy database in Germany suggested that the annual transition rates from advanced adenoma (adenomas ≥ 1 cm, tubulovillous or villous adenomas, adenomas with high-grade dysplasia) to cancer is comparable among women and men, but strongly increases with age.¹⁴ Projected annual transition rates from advanced adenoma to cancer increased from 2.6% in age group 55 to 59 years to 5.1% in age group 80 and older among men, for example. These estimated rates in older age groups are in line with previous estimates derived from small case series but are considerably lower for younger age groups.

Both longitudinal follow-up of a small number of people with unresected adenomas and studies of age distribution provide indirect evidence that the evolution from adenoma to carcinoma takes at least 5 to 10 years. Age prevalence data from the National Polyp Study, for example, suggest that it may take as long as 5 to 10 years for normal-appearing mucosa to develop into a macroscopically visible adenomatous polyp, and an additional 3 to 5 years for invasive carcinoma to develop, in most instances. Case-control studies also support that the development of adenomas in the colon and the evolution to carcinoma occur slowly. Several studies have estimated

that a significant protective effect of screening sigmoidoscopy may last at least 10 years.¹⁵

Associated Disease States. A number of clinical situations have been associated with a greater than average risk for adenoma development, but the evidence in most cases is tenuous. Although adenomas and carcinomas develop frequently in patients who have undergone urinary diversion by way of ureterosigmoidoscopy, this is largely of historical interest. Nonetheless, patients who have undergone this procedure require periodic colonoscopic surveillance for adenoma and carcinoma development. An increased prevalence of colonic adenomas and carcinomas has been reported in patients with acromegaly, and patients with elevated gastrin levels have been reported to be at risk for neoplasia. Alleged associations between colorectal adenomas and a history of prior cholecystectomy, atherosclerosis, acrochordons (skin tags), and hyperplastic polyps remain unproven.

Clinical Features

Adenomatous polyps of the colon and rectum are highly prevalent in Western societies, but most patients with colonic adenomas do not have symptoms directly referable to these lesions. Overt bleeding manifesting as hematochezia may occur with larger polyps, which may be evident when the polyps are located distally in the rectum. Adenomas typically lose less than 1 mL of blood daily unless they are 2 cm or larger in size. Although colorectal polyps are the most common lesions detected in patients without symptoms undergoing colonoscopy because of the presence of fecal occult blood, the polyps are probably not responsible for the bleeding. Very large colonic polyps may be associated with obstructive symptoms, such as lower abdominal cramping or alterations in bowel habits, but this is unusual. Secretory diarrhea with accompanying hypokalemia and hypochlorhydria has been associated with very large villous adenomas of the distal colon and rectum. This is a rare syndrome, and the search for secretagogues such as vasoactive intestinal polypeptide or prostaglandins in patients with polyps and diarrhea is infrequently productive.

Adenomas Associated with Lynch Syndrome and Its Variants

Lynch syndrome is a disease of autosomal dominant inheritance in which cancers arise in discrete adenomas, but polyposis (i.e., dozens or hundreds of polyps) does not occur. Initial case findings used the Amsterdam criteria, but these are not required to make the diagnosis of Lynch syndrome. The Amsterdam criteria identify families who have at least three relatives with colorectal cancer, one of whom is a first-degree relative of the other two; colorectal cancer must involve at least two generations; and at least one cancer case must occur before 50 years of age. Broader definitions of Lynch syndrome take into account the occurrence of extracolonic tumors and smaller kindreds.¹⁶ Currently, the diagnosis of Lynch syndrome is made by finding a germline mutation in the DNA mismatch repair gene, not by clinical criteria. Adenomas and carcinomas in Lynch syndrome arise at an early age (adenomas may occur in patients in their 20s and 30s, with a mean age for carcinoma development of 40 to 45 years) and the polyps are often proximal in location and multiple. Women with Lynch syndrome are prone to cancers of the female genital tract (endometrium and ovary) in addition to colorectal neoplasms. The frequency of Lynch syndrome in the general population is difficult to determine, but Lynch syndrome accounts for about 3% to 4% of all colorectal cancer cases; this suggests that Lynch syndrome may occur in about 2 to 5 per 1,000 of the population.

Turcot syndrome is a term of historical significance, in which there is a concurrence of primary brain tumors and multiple colorectal adenomas or cancer in young people. With the advent of accurate genetic characterization, these families may be categorized as either FAP or Lynch syndrome, as brain tumors are an occasional complication of both diseases.¹⁷

Diagnosis

Most colorectal adenomas are asymptomatic and often are detected in the setting of an evaluation for unrelated colonic symptoms or occult blood in the stool. Similarly, adenomatous polyps frequently are detected when patients without symptoms are screened for colorectal neoplasia. Nevertheless, data strongly suggest that the detection and removal of adenomatous polyps are important in reducing colorectal cancer-related mortality.

- 4 In 2008, a joint guideline on screening and surveillance for early detection of colorectal cancer and adenomatous polyps was issued by the American Cancer Society (ACS), the U.S. Multi-Society Task Force on Colorectal Cancer (USMTF), and the American College of Radiology (ACR).¹⁸ This update of previous guidelines is notable in that it grouped screening tests into those that primarily detect cancer (annual fecal occult blood tests [FOBTs] including those that are guaiac based or immunochemical, and stool DNA tests, interval not specified) and those that can detect early cancer and adenomatous polyps (flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, double-contrast barium enema every 5 years, or computed tomography [CT] colonography every 5 years). In November 2008, the U.S. Preventative Services Task Force (USPSTF) also issued updated guidelines (Table 67.2).¹⁹ Based on a targeted evidence-based review and a decision analytic modeling analysis, the USPSTF recommended screening of average-risk individuals age 50 to 75 years with high-sensitivity FOBTs annually, sigmoidoscopy every 5 years plus FOBTs every 3 years, or colonoscopy every 10 years. Notably, the USPSTF indicated that while the benefits of screening outweigh the potential harms for 50- to 75-year-olds, the likelihood that detection and early intervention will yield a

mortality benefit declines after age 75 because of the long average time between adenoma development and cancer diagnosis. Routine screening was therefore not recommended for adults age 76 to 85 years, and screening was not recommended at all in adults older than 85 years of age. These guidelines also indicated that for all populations there is insufficient evidence to assess the benefits and harms of screening with CT colonography or fecal DNA testing.

Fecal Occult Blood Tests. Screening studies from both Europe and the United States indicate that a polyp is detected in about 30% of patients without symptoms who are 50 years of age or older and undergo colonoscopy for follow-up of a positive fecal occult blood test result. Blood loss from polyps is related to polyp size, and positive fecal occult blood test results are related to polyp size and proximity to the rectum. In one study in which rehydrated Hemoccult slides were used (rehydration results in greater sensitivity but also increases the number of false-positive findings), only 15% of polyps smaller than 1 cm were associated with a positive Hemoccult test result, whereas 80% of polyps larger than 2 cm were associated with a positive result. In another study, standard testing with Hemoccult cards detected 17% of adenomas smaller than 1 cm and 42% of adenomas larger than 1 cm. A prospective randomized study of fecal occult blood tests in which rehydrated Hemoccult cards were used indicated that annual testing reduces colorectal cancer-related deaths by 33% through 18 years of follow-up.²⁰ This study, in addition to two European trials, has also demonstrated a 15% to 21% reduction in colon cancer-related death from biennial fecal occult blood testing.²¹ Thus, unless one rigorously performs the fecal occult blood test on an annual basis, the reduction in colorectal cancer mortality will be disappointing.

Methods that may decrease the false-positive FOBT rates while maintaining or increasing sensitivity currently are being refined and compared for efficiency with Hemoccult-type slide tests. Fecal immunochemical tests (FITs) are designed to detect human globin and are not affected by diet or drugs. Strategies that use an immunochemical-based FOBT have been shown to be cost-effective when used for colorectal cancer screening in Asia. Quantitative immunochemical FOBT has been shown to

^aU.S. Preventive Services Task Force. Screening for colorectal cancer: US Preventative Services Task Force recommendation statement. *Ann Int Med* 2008;149:627–637. The U.S. Preventative Services Task Force recommends screening for adults age 50 to 75 years. Screening for adults age 76 to 85 is not routinely recommended, and for adults older than 85 years screening is not recommended.

^bLevin B, Lieberman DA, McFarland B, et al. Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps 2008: a joint guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. *CA Cancer J Clin* 2008;58:130–160. Testing options are divided into those that detect adenomatous polyps and cancer (flexible sigmoidoscopy, colonoscopy, double-contrast barium enema, computed tomography colonography) and those that primarily detect cancer (FOBT, stool DNA testing).

have good sensitivity and specificity for detection of clinically significant neoplasia in recent studies of asymptomatic and symptomatic individuals, but test performance in prospective screening programs has been less well studied. Fecal immunochemical tests have, however, been included in recent screening guidelines (see earlier).

Results from the National Polyp Study strongly indicate that the removal of index polyps detected by fecal occult blood testing and other methods, together with subsequent colonoscopic surveillance, results in a very substantial reduction in colorectal cancer mortality; in fact, the reduction may be as high as 76% to 90% (see later).²²

Sigmoidoscopy. The benefit of sigmoidoscopy in interrupting the adenoma-to-carcinoma sequence is suggested by a number of studies. Investigators compared the use of rigid sigmoidoscopy in 261 members of the Kaiser Permanente Medical Care Program who died of cancer of the rectum or distal colon versus that in 868 matched controls.¹⁵ Only 8.8% of those with cancer had undergone screening sigmoidoscopy, compared with 24.2% of controls. The impact of sigmoidoscopy was limited to the development of fatal colon cancer within reach of the sigmoidoscope and was long-standing (at least 10 years). Other investigators determined the long-term risk of colorectal cancer development after rigid sigmoidoscopy and polypectomy in 1,618 patients with rectosigmoid adenomas. The overall risk for subsequent rectal cancer in these patients was similar to that in the general population, but subject analysis revealed that risk depended on histologic type, size, and number of adenomas removed.²³ The 60-cm flexible sigmoidoscope has supplanted the rigid scope because it causes less discomfort to the patient, visualizes 2.5 times more surface area, and detects two to three times more adenomas. Flexible sigmoidoscopy can be mastered by paramedical personnel and has been successfully used in screening programs by nurse practitioners. Randomized controlled trials are now under way to measure the effect of screening with flexible sigmoidoscopy on colorectal cancer mortality. The Prostate, Lung, Colon, and Ovarian Cancer Screening Trial (PLCO) has enrolled 155,000 individuals in a recent prospective randomized trial that compares flexible sigmoidoscopy to a usual-care control group. Follow-up is planned through 2015 with cancer-related mortality as the major endpoint. Recent joint guidelines from the American Cancer Society, the U.S. Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology include flexible sigmoidoscopy every 5 years as a screening option, while the USPSTF guidelines include flexible sigmoidoscopy every 5 years in conjunction with high-sensitivity FOBT every 3 years.

Colonoscopy, Barium Enema, Computed Tomography Colonography, and Stool DNA Testing. Colonoscopy may well be the most effective tool for screening for colorectal neoplasia (and especially adenomas), but data from prospective randomized trials are lacking. The National Polyp Study of polypectomy and surveillance strongly suggested a reduction in colorectal cancer mortality as a result of removing adenomatous polyps compared to historic reference populations. A Canadian population-based study compared the risk of developing colorectal cancer after a negative colonoscopy in all Ontario residents with a history of a complete negative colonoscopy with controls consisting of the Ontario population without a history of colonoscopy.²⁴ In the negative colonoscopy cohort, the relative risk of distal colorectal cancer was significantly lower than the control group in each of the 14 years of follow-up, while the relative risk for proximal colorectal cancer was significantly lower mainly during the last 7 years of follow-up. A second Canadian case-control study demonstrated that complete colonoscopy was also associated with fewer deaths from left-sided colorectal cancer, but not from right-sided cancer. These findings are of interest in light of arguments that colonoscopy is

preferable to sigmoidoscopy, because there may be a substantial incidence of proximal colon cancers and advanced adenomas beyond the reach of the sigmoidoscope. Some of these individuals may not have distal findings on sigmoidoscopy that would trigger a subsequent colonoscopy. Two trials^{25,26} suggested that approximately 50% of individuals with advanced proximal neoplasms (adenoma >1 cm; adenoma with villous features or dysplasia; cancer) have no distal neoplasms. Fewer than 2% of those who did not have distal neoplasms, however, had an advanced proximal lesion. A decision analysis commissioned by the USPSTF supports colonoscopy every 10 years as a screening option measured in life-years gained, and the joint guidelines authored by the ACS, USMTE, and ACR suggest colonoscopy as a means of preventing colorectal cancer through adenoma detection and removal.

High-contrast endoscopy using dye or stain solutions combined with colonoscopy (chromoendoscopy) or high-resolution optical methods (e.g., narrow-band imaging, laser confocal endoscopy) has been suggested as a means of identifying lesions in high-risk groups or as an adjunct to colonoscopy where flat lesions (so-called “flat adenomas”) are suspected. Recent evidence suggests that flat or depressed neoplasms are more common than previously appreciated and carry a high relative risk of containing in situ or invasive carcinoma.²⁷

Air-contrast barium enema (ACBE) has been included as an option in a variety of screening guidelines. No studies, however, have directly addressed the effectiveness of barium enema for colon cancer screening, and especially for detection of adenomas. Several studies have indicated that the sensitivity of ACBE is less than that of colonoscopy, especially for detecting lesions less than 1 cm. A recent population-based study suggested that if a cancer is present, there is approximately a one in five chance that it will be missed by ACBE.

CT colonography, or “virtual” colonoscopy, involves the use of helical CT to generate high-resolution images of the abdomen and pelvis. CT colonography has the potential advantage of being a rapid and safe method of providing full structural evaluation of the entire colon. Two trials provide evidence that CT colonography may be a valid alternative for primary colon cancer screening. The National CT Colonography Trial²⁸ directed by the American College of Radiology Imaging Network (ACRIN) was a multicenter study that employed CT colonography and same-day colonoscopy using a standard matching protocol in 2,600 asymptomatic individuals. Per patient sensitivity of CT colonography for adenomas greater than 10 mm was 90% with a negative predictive value of 99%. A second trial²⁹ compared CT colonography and optical colonoscopy in parallel screening cohorts and demonstrated similar rates of detection of advanced neoplasia in both groups. Several key issues need to be addressed as the use of CT colonography becomes more widespread, principal among which is determination of the acceptable size cut-off of a lesion detected by CT colonography that will necessitate a follow-up colonoscopy.

A great deal of knowledge has been accumulated recently about genetic alterations that occur during colon carcinogenesis (discussed earlier). A molecular approach to colorectal cancer screening is therefore attractive since it targets biologic changes that are fundamental to the neoplastic process. Fecal DNA testing relies on the detection of genetic alterations in DNA shed into the stool from neoplastic lesions. While small studies utilizing specimens from patients with known lesions have been promising, larger prospective trials using fecal DNA marker panels have been, to date, disappointing, especially in detecting adenomas. A recently published study³⁰ compared stool DNA and FOBT for detection of “screen-relevant neoplasia” (curable stage cancer, high-grade dysplasia, or adenomas >1 cm). This blinded, multicenter, cross-sectional study used two different methodologies for detecting alterations in stool DNA, a 23-marker panel and a new test targeting three broadly informative markers (point mutations on *K-ras*, a

FIGURE 67.6. Endoscopic snare polypectomy. **A:** A small colonic polyp. **B:** The polypectomy snare is placed around the polyp. **C:** The snare is closed around the base of the polyp, and the head of the polyp is gently pulled away from the wall and into the lumen. Current is applied to cut the stalk and cauterize the site. **D:** The site after completion of polypectomy.

scanned mutation cluster region of *APC*, and methylated vimentin). While the multipanel test provided no improvement over FOBT (Hemoccult Sensa) for detection of screen-relevant neoplasms, the newer test showed promise by detecting significantly more neoplasms than FOBT.

Management of Adenomas

Index Polypectomy. Once detected, adenomas should be completely removed, preferably by endoscopic snare polypectomy (Fig. 67.6). Polypectomy is relatively safe and easily performed when adenomas are small or pedunculated but is more difficult when polyps are large or sessile. Potential complications include bleeding and perforation of the polypectomy site. Large sessile villous adenomas (>2 cm) have a great potential for malignant degeneration. If such lesions cannot be completely removed by snare polypectomy, and when there is uncertainty about the polypectomy margin in the case of pathologically advanced lesions, segmental surgical resection may be necessary. Diminutive polyps, on the other hand, carry little malignant potential. If they are too small for snare polypectomy, ablation with a hot biopsy forceps is a reasonable approach. Because 30% to 50% of patients with one adenoma have a synchronous adenoma elsewhere in the colon, the entire colon should be “cleared” by colonoscopy in polyp-bearing patients.

Follow-up. Much of our current practice has come from information gained through the National Polyp Study (NPS), first organized in 1978. Additional metachronous adenomas are likely to develop in patients who have had adenomas removed. Colonoscopic surveillance studies have provided estimates of the frequency and time course of recurrence in these patients. Data from the NPS suggested a recurrence rate of 32% to 42% by 3 years after index polypectomy. A prospective colonoscopic analysis also demonstrated a cumu-

lative recurrence rate at 3 years of 42%. Most adenomas detected at this 3-year interval were small tubular adenomas. Age above 60 years, multiple adenomas at index polypectomy, and large size of the index adenoma predicted polyp recurrence in the NPS, but only multiplicity predicted recurrence of polyps with advanced pathologic features (i.e., >1 cm, high-grade dysplasia, or invasive cancer) at follow-up. The 3-year recurrence rate in patients with a known history of adenoma (42%) was higher than the incidence rate of adenoma appearance *de novo* during this period in patients who had no adenomas detected on index colonoscopy (16%).²²

The high recurrence rate of adenomas after index polypectomy supports the use of postpolypectomy surveillance in patients with known histories of adenoma. Colonoscopy is the preferred means of follow-up in these patients. Air-contrast barium enemas are inadequate for surveillance exams; they will miss a substantial number of large lesions and most small polyps. Barium enema will likely be supplanted by the use of CT colonography, as discussed earlier. Colonoscopy is the most accurate means of evaluating the colonic mucosa, and most importantly, allows biopsy and removal of polyps.

Data from the NPS indicate that colonoscopy need not be repeated at intervals shorter than 3 years in patients whose index polyp demonstrates no evidence of high-grade dysplasia or carcinoma. Although patients undergoing postpolypectomy surveillance at both 1 and 3 years after index polypectomy had a greater number of polyps detected in this study than did those undergoing colonoscopy at 3 years only, the percentage of patients whose adenomas had advanced pathologic features was similarly low in both groups (3.3%). Subsequent studies have confirmed the low incidence of recurrent advanced adenomas 3 to 5 years after polypectomy. One recent study examined the relative risk for advanced neoplasia within 5.5 years of a baseline colonoscopy.³¹ There was a strong association between the results of baseline screening colonoscopy and the rate of serious incident lesions during surveillance. This study confirmed that patients with one or two small tubular adenomas represent a low-risk group compared with other patients with colorectal neoplasia.

Table 67.3 lists the 2008 ACS/USMTF/ACR guidelines for screening, surveillance, and early detection of colorectal adenomas and cancer for individuals at increased risk or at high risk of disease. These guidelines suggest that those whose index lesion consists of one or two small tubular adenomas with low-grade dysplasia should have a follow-up colonoscopy 5 to 10 years after the initial polypectomy. The precise timing within this interval should be based on clinical factors (prior findings, family history, patient and physician preferences). In those with a large (>1 cm) adenoma, multiple (3 to 10) adenomas, or adenomas with high-grade dysplasia or villous change, colonoscopy should be repeated within 3 years after the initial polypectomy. Although the risk for recurrence of advanced adenomas at this follow-up interval is greater in patients with high-risk adenomas than those with low-risk adenomas, the incremental risk is small.³² If the exam is normal or shows only one or two small tubular adenomas with low-grade dysplasia, then the interval for the subsequent exam should be 5 years. Patients with more than 10 adenomas on a single examination should have a follow-up colonoscopy less than 3 years after the initial polypectomy and the presence of an underlying familial syndrome should be considered. Patients with sessile adenomas that are removed piecemeal should have follow-up colonoscopy in 2 to 6 months to verify complete removal.

Management of Malignant Polyps

Endoscopic polypectomy is adequate treatment for an adenomatous polyp containing cancer if it can be demonstrated that the cancer is confined to the head of the polyp (i.e., carcinoma

TABLE 67.3

GUIDELINES FOR THE SURVEILLANCE OF ADENOMAS IN PEOPLE AT INCREASED OR HIGH RISK FOR COLORECTAL CANCER

■ RISK CATEGORY	■ AGE TO BEGIN SURVEILLANCE	■ RECOMMENDATION	■ COMMENT
Increased Risk: Patients with History of Adenomas at Prior Colonoscopy			
Patients with one or two small tubular adenomas with low-grade dysplasia	5–10 y after initial polypectomy	Colonoscopy	Precise timing based on clinical factors, patient and physician preferences
Patients with 3–10 adenomas or one adenoma >1 cm or any adenoma with villous features or high-grade dysplasia	3 y after initial polypectomy	Colonoscopy	If follow-up exam is normal or shows one or two small tubular adenomas, subsequent exam at 5 y
Patients with >10 adenomas on a single examination	<3 y after initial polypectomy	Colonoscopy	Consider familial CRC syndrome
Patients with sessile adenomas that are removed piecemeal	2–6 mo to verify complete removal	Colonoscopy	Surveillance individualized based on endoscopist's judgment
Increased Risk: Patients with Family History			
CRC or adenomatous polyps in a first-degree relative before age 60 years or in two or more first-degree relatives at any age	Age 40 or 10 y before the youngest case in the immediate family	Colonoscopy	Every 5 y
Either CRC or adenomatous polyps in a first-degree relative age ≥60 y or in two second-degree relatives with CRC	Age 40 y	Screening options at intervals recommended for average-risk individuals	Screening should begin at an earlier age, but individuals may be screened with any recommended form of testing
High Risk			
Genetic diagnosis of FAP or suspected FAP without genetic testing evidence	Age 10–12 y	Annual FSIG to determine if the individual is expressing the genetic abnormality and counseling to consider genetic testing	If the genetic test is positive, colectomy should be planned
Genetic or clinical diagnosis of Lynch syndrome, or individuals at increased risk of Lynch syndrome	Age 20–25 y or 10 y before the youngest case in the immediate family	Colonoscopy every 1–2 y and counseling to consider genetic testing for inherited DNA MMR	Genetic testing for Lynch syndrome should be offered to first-degree relatives of persons with a known gene mutation. It should also be offered when the family mutation is not known but one of the first three of the modified Bethesda criteria is present.

CRC, colorectal cancer; FAP, familial adenomatous polyposis; FSIG, flexible sigmoidoscopy; MMR, mismatch repair. Derived from Levin B, Lieberman DA, McFarland B, et al. Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps 2008: a joint guideline from the American Cancer Society, the Multi-Society Task Force on colorectal cancer and the American College of Radiology. *CA Cancer J Clin* 2008;58:130–160.

in situ or intramucosal carcinoma; Fig. 67.7). The adequacy of simple polypectomy has been controversial in cases in which malignant cells have invaded the polyp stalk (Fig. 67.8), but most studies indicate that polypectomy is adequate treatment provided that a margin of more than 2 mm is present, the cancer is not poorly differentiated, and no vascular or lymphatic invasion is noted. The presence of cancer at or near the margin is significantly associated with an adverse outcome, even in the absence of other unfavorable parameters. On the other hand, in the absence of unfavorable histology and with a negative margin, the incidence of residual cancer is low (<1%). These criteria are more difficult to assess in sessile polyps. If an adequate margin cannot be demonstrated or negative histologic parameters are present, surgery is recommended to treat the possibility of regional lymph node metastases.

Primary Prevention of Adenoma Recurrence

Primary prevention relates to the ability to identify genetic, environmental, and biologic factors that cause cancer, and to alter their effects. Laboratory, clinical, and epidemiologic evidence suggests that the regular use of nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, is associated with a decreased risk for the development of colorectal cancer. Four recently published trials have demonstrated a reduction in adenoma recurrence in chemoprevention trials involving aspirin.^{33,34} Given biologic plausibility, preclinical in vitro and animal data, and data on adenoma regression in patients with FAP, three large randomized trials, which in total studied over 6,000 patients, were undertaken to examine the effect of

FIGURE 67.7. Diagram representation of cancer-containing polyps. Pedunculated adenoma is described on the left and a sessile adenoma on the right. In carcinoma in situ, malignant cells are confined to the mucosa. These lesions are adequately treated by endoscopic polypectomy. Polypectomy is adequate treatment for invasive carcinoma only if the margin is sufficient (2 mm), the carcinoma is not poorly differentiated, and no evidence of venous or lymphatic invasion is found. (After Haggitt RC, Glotzbach RE, Soffen EE, et al. Prognostic factors in colorectal carcinomas arising in adenomas: implications for lesions removed by endoscopic polypectomy. *Gastroenterology* 1985;89:328.)

cyclooxygenase-2 (COX-2)-selective inhibitors on new adenoma formation in individuals with a history of sporadic adenomas. All of these trials demonstrated a highly significant reduction in new adenoma formation in those taking a COX-2-selective inhibitor (celecoxib, rofecoxib) compared to placebo over 3 years. In the Adenoma Prevention with Celecoxib (APC) trial,³⁵ for example, use of celecoxib was associated with a dose-dependent 33% to 45% reduction in the development of new adenomas overall by 3 years, with a 57% to 66% reduction in the number of patients developing advanced adenomas. Unfortunately, adverse thrombotic cardiovascular events were associated with COX-2 inhibition in at least two of these trials. Recent data suggest that increased cardiovascular risk may be associated with most NSAIDs, and not just COX-2 inhibitors.

Other agents currently undergoing study for chemoprevention of colorectal neoplasia include the ornithine decarboxylase inhibitor difluoromethylornithine (DFMO), the bile acid ursodiol, the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors such as pravastatin and lovastatin, epidermal growth factor receptor (EGFR) inhibitors, and matrix metalloproteinase (MMP) inhibitors. The combination of DFMO and the NSAID sulindac were studied in a

randomized placebo-controlled trial to assess their efficacy in preventing sporadic adenoma recurrence in 375 subjects. Use of this regimen was associated with a 70% reduction in new adenomas at 3 years compared to placebo.³⁶ Larger studies are needed to confirm this result and to fully assess toxicity of this combination. A population-based case-control study of individuals with colorectal cancer and matched controls demonstrated a 47% relative reduction of colorectal cancer associated with statin use, but further investigation is needed to assess the overall benefits of this group of agents.

Supplemental calcium reduces proliferative activity in the mucosa of experimental animals and patients at high risk for the development of colorectal cancer. A large body of observational and laboratory studies suggests a role for dietary calcium supplementation in chemoprevention. A prospective, double-blind, placebo-controlled trial showed that supplemental calcium (3,000 mg of calcium carbonate per day, equivalent to 1,200 mg of elemental calcium) reduced the incidence and number of recurrent adenomas in subjects chosen for a recent history of such lesions. The protective effect of calcium supplementation on the risk of colorectal adenoma recurrence extended up to 5 years after cessation of active treatment, even in the absence of continued supplementation.³⁷ Analysis of

FIGURE 67.8. Invasive carcinoma in the stalk of an adenomatous polyp. **A:** Low-power view. Malignant glands can be seen invading fibrovascular stalk. **B:** High-power magnification of malignant glands in stalk. Nuclei are large, hyperpigmented, and crowded.

serum vitamin D status in subjects suggested that calcium supplementation and vitamin D status appear to act together to reduce the risk of adenoma recurrence.

Trials of supplemental dietary fiber, as well as antioxidant vitamins such as β -carotene and vitamins C and E, have not convincingly demonstrated any effect on adenoma recurrence.

NONNEOPLASTIC MUCOSAL POLYPS

Hyperplastic Polyps

Hyperplastic polyps are small, usually sessile lesions most frequently encountered in the distal colon and rectum (Fig. 67.9A). Although grossly indistinguishable from small adenomas, they carry no significant potential for malignant degeneration particularly when located in the distal colon or rectum. However, hyperplastic polyps must be distinguished from serrated adenomas, which carry significant malignant potential (see later). Macroscopically, these polyps are almost always less than 1 cm in size, and most are in the distal colon. In fact, when hyperplastic polyps are found proximal to the rectosigmoid region, one must consider the possibility of a serrated adenoma. Microscopically, hyperplastic polyps are characterized by a saw-toothed epithelial pattern representing micropapillary luminal infoldings of columnar absorptive cells and mature, frequently hyperdistended goblet cells (Fig. 67.9B). Elongation and subsequent infolding of the epithelium may be caused by an expanded, but otherwise normally located, replication zone in the crypt. The cytologic atypia found in adenomatous polyps is not seen in these lesions.

Hyperplastic polyps are common age-related lesions found in about one third of the population older than 50 years. Although they often coexist with adenomas in polyp-bearing patients, no convincing evidence has been found that hyperplastic polyps per se are harbingers of adenoma development. Because hyperplastic polyps are asymptomatic and carry no malignant potential, no specific treatment is required for these lesions. If a hyperplastic polyp is the only lesion detected on index flexible sigmoidoscopy or colonoscopy, no further evaluation is indicated.

Serrated Adenomas

Serrated adenomas are polyps that have the dysplastic cytologic features of an adenoma and the serrated surface features of the hyperplastic polyp. These often occur proximal to the rectosigmoid region and may become larger than 1 cm. These will create difficult diagnostic decisions for even the best pathologists. There is evidence that large serrated polyps in the proximal colon may be the precursors to colorectal cancers of the MSI phenotype. Thus, good clinical judgment would suggest that, whereas the small hyperplastic polyps commonly seen in the distal colon should not be a trigger for colonoscopic surveillance, larger serrated polyps in the proximal colon should raise clinical concerns and be followed up like an advanced adenoma.³⁸

Juvenile Polyps

Juvenile polyps, also known as *retention polyps*, can occur sporadically or as part of a familial polyposis syndrome. These mucosal polyps consist of dilated cystic mucus-filled glands and abundant lamina propria with an inflammatory infiltrate. Seventy-five percent of these occur in children younger than 10 years of age, often appearing as single pedunculated cherry-red polyps with a smooth surface and contour. The exact prevalence of such lesions has not been determined, but they are thought to be acquired lesions detectable in about 2% of children who do not have symptoms. Juvenile polyps often present in the form of hematochezia because they are highly vascularized lesions. Rectal prolapse and autoamputation may occur with distal lesions, whereas intussusception may be precipitated by proximal juvenile polyps found in the context of familial syndromes. Individually, these polyps have no malignant potential, but symptomatic polyps should be removed to prevent further complications. Juvenile polyposis, on the other hand, is associated with an increased risk for the early development of cancer.

Inflammatory Polyps

Inflammatory mucosal polyps are common in the setting of idiopathic inflammatory bowel disease. Marked inflammation

FIGURE 67.9. Hyperplastic polyps. **A:** Several diminutive hyperplastic polyps seen in the rectum during flexible sigmoidoscopy. **B:** Photomicrograph of a hyperplastic polyp, characterized by elongated glands with papillary infoldings that have a typical serrated epithelial pattern.

FIGURE 67.10. Inflammatory polyps. **A:** Severe mucosal inflammation with infiltrates and granulation tissue shown here microscopically can appear clinically with a polypoid configuration. **B:** Resolution of inflammation can leave exuberant polyps covered by normal epithelium, which are called pseudopolyps, a misnomer. These are truly polyps, but are not neoplastic.

and ulceration coexist with granulation tissue in a distorted mucosal architecture that appears polypoid because of confluent areas of ulceration, leaving behind islands of intact epithelium (Fig. 67.10A). Subsequent healing leads to the appearance of polypoid, nonneoplastic excrescences covered by normal colonic epithelium, so-called pseudopolyps (Fig. 67.10B). They need not be removed and are important largely because they make it difficult to recognize subtle, early neoplastic lesions in these high-risk patients. Severe chronic inflammation of any kind, including a variety of infectious diseases (tuberculosis, amebiasis, schistosomiasis, amebic colitis), may result in inflammatory polyps that resemble those found in idiopathic inflammatory bowel disease.

Submucosal Polyps

Submucosal masses can expand to push the colonic mucosa into the bowel lumen and thus appear as polypoid lesions. Many submucosal lesions (e.g., lipomas, leiomyomas) are clinically asymptomatic and must be differentiated from neoplastic lesions. Others are malignant lesions that require early detection, such as lymphomas and metastatic tumors. Many submucosal lesions are not detected on endoscopic mucosal biopsy because standard biopsy forceps do not reach beyond the mucosa. If a submucosal lesion is suspected, multiple biopsy specimens of the same site sometimes provide tissue for diagnosis.

Lipomas are benign fatty tumors that occur throughout the gastrointestinal tract but are most commonly found in the cecum near the ileocecal valve (Fig. 67.11). They appear endoscopically as soft, smooth polyps that are pliable and deformable. The overlying mucosa is intact but may be light yellow in appearance. These are benign lesions that have little clinical significance and are commonly seen in obese patients.

Isolated **lymphoid nodules** consisting of benign lymphoid tissue may appear as sessile smooth polyps of various sizes, with a predilection for the distal colon and rectum. These are usually asymptomatic. Diffuse nodular lymphoid hyperplasia also occurs in children as an incidental finding. The nodules must be distinguished from primary or secondary lymphoma of the large intestine, which may present as mucosal nodular-

ity resembling the pseudopolyposis of inflammatory bowel disease or even polyposis (Fig. 67.12). Flow cytometry of the lymphocytes in the lesion will be helpful; benign polyposis is polyclonal, whereas lymphomas are monoclonal and may overexpress cyclin D.

Pneumatosis cystoides intestinalis consists of multiple air-filled cysts within the submucosa. This may be an incidental finding in patients with chronic obstructive pulmonary disease, scleroderma, or asymptomatic pneumoperitoneum secondary to recent surgery or instrumentation, in which air or colonic gas diffuses into the cysts. These sometimes resolve with administration of oxygen. A far more virulent form of pneumatosis is associated with fulminant mucosal inflammation, ischemia, or necrotizing enterocolitis in children. These cysts are thought to result from mucosal invasion by gas-producing bacteria.

Colitis cystica profunda is a rare condition in which the intestinal wall is thickened by submucosal mucus-filled cysts of various sizes and an accumulation of fibroblasts in the lamina propria. It can present as an ulcerating or mass lesion in the rectosigmoid in association with the solitary rectal ulcer syndrome. Although the pathogenesis of this condition is unknown, it may result from the downward displacement of colonic glands during trauma or chronic inflammation followed by healing. The appearance of aberrant submucosal glandular epithelium and acellular mucous lakes must be distinguished from a colloid carcinoma, because this lesion has no malignant potential.

Carcinoid tumors of the rectum appear as isolated, small, yellow-gray submucosal nodules. These are often incidental findings during sigmoidoscopy. Most are smaller than 1 cm, have little malignant potential, and are amenable to local excision. Lesions larger than 2 cm are more likely to be malignant but seldom give rise to metastases. These lesions should be treated aggressively with complete excision. Rectal carcinoid tumors are usually asymptomatic but may present with hematochezia. They are not associated with the carcinoid syndrome. Carcinoid tumors in the proximal colon may be locally invasive or metastasize to the liver, liberating vasoactive peptides into the systemic circulation and producing the carcinoid syndrome.

Other lesions that can present as submucosal polyps include **metastatic tumors**, such as malignant melanoma, and benign lesions, such as **leiomyomas**, **fibromas**, **lymphangiomas**, **hemangiomas**, and **endometriosis**.

GASTROINTESTINAL POLYPOSIS SYNDROMES

Gastrointestinal polyposis indicates the presence of a systemic process that promotes the development of multiple polyps throughout the gastrointestinal tract. In some instances, the polyps are located predominantly in the colon; however, in others, polyps may be found in the stomach, small intestine, colon, and rectum. The classification of the polyposis syndromes has traditionally been based on the histologic characteristics of the polyps, but gradually an awareness of the genetic basis for the most important of these syndromes has permitted more precise diagnosis and rational approaches to treatment.

Familial Adenomatous Polyposis

FAP is an autosomal dominant, genetic disease characterized by the development of multiple adenomatous polyps throughout the colon and rectum (Fig. 67.13). The polyps first appear in adolescence, with the median age of onset being about 16 years. The number of polyps in each patient is variable, and they increase in number and size with advancing age. The genetic basis for this disease is a germline mutation in the *APC* gene located on chromosome 5q. In part, the age of onset, number of polyps, and age at which cancer develops are determined by the location of the mutation in the *APC*

gene (Fig. 67.14). More than 5,000 polyps can develop in patients with specific *APC* mutations, and cancer develops in these patients at a mean age of 35 years. Other mutations in the *APC* gene can give rise to attenuated forms of the disease in which only a few (i.e., 20 to 100) polyps are likely, and the median age for cancer development may be in the 50s or 60s. Additional factors not related to the mutation on the *APC* gene, some genetic and some environmental, also modify the clinical characteristics of the disease.^{39,40}

Gastrointestinal Features. Polyps in the stomach and small intestine develop in about 90% of patients with FAP. The gastric polyps consist of fundic gland polyps, which are not premalignant lesions. These may appear to be dysplastic, but in the Western world (North America and Europe), gastric cancer occurs in fewer than 1% of FAP patients. Gastric cancer is a bigger diagnostic problem in FAP in Japan and Korea, however.

Small-intestinal neoplasia is not rare in FAP and principally occurs in the periampullary region of the duodenum. Duodenal adenomatous polyps, which typically appear later than the colonic lesions, may be multiple but tend not to carpet the proximal small intestine. The ampulla of Vater is a particular target for neoplastic development. With time, carcinoma develops in up to 5% to 10% of these patients, so that duodenal surveillance is required. Spigelman has developed a classification system that can be used to determine optimal surveillance for duodenal neoplasia, which is based on the number, size, and histologic features of the duodenal polyps (Table 67.4).

FIGURE 67.13. Familial adenomatous polyposis (FAP). A: Gross specimen of a resected colon from a patient with FAP. B: Sessile and pedunculated adenomatous polyps in the colon of a patient with FAP. C: Close-up view of a profuse type of FAP, in which the mucosa is carpeted with innumerable polyps. D: Photomicrograph demonstrating profuse FAP with both sessile and pedunculated adenomatous polyps.

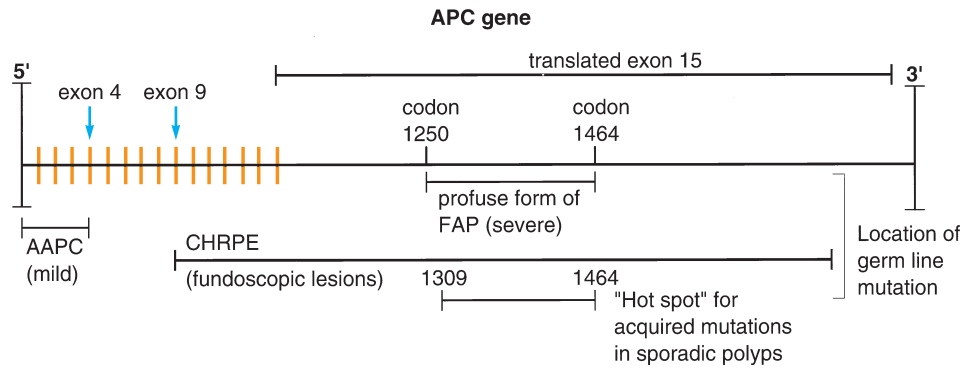

FIGURE 67.14. This scheme of the APC (adenomatous polyposis coli) gene illustrates the genotype-phenotype correlations. Most mutations of APC result in premature stop codons; therefore, the site of the mutation usually indicates the relative length of the mutant protein product. Mutations at the 5' end of the gene produce "attenuated" FAP, a milder form of the disease. The retinal lesions (congenital hypertrophy of retinal pigmented epithelium [CHRPE]) occur when the mutations are between exons 9 and 15. The portion of the APC gene that binds to other cytoskeletal elements in the cell is represented at the 3' end of the 15th exon. Mutations in a hot spot immediately downstream from the β -catenin-binding site (between codons 1250 and 1464) result in a more virulent, profuse form of familial adenomatous polyposis. This site is also the location of most of the acquired mutations in sporadic colorectal neoplasms.

Adenomas and carcinomas occur in the jejunum and ileum, but these are rare. Polyps in the terminal ileum may represent lymphoid aggregates rather than adenomas and should be biopsied for diagnostic purposes.

Classically, it has been stated that the natural history of FAP is for cancer to develop at a median age of about 40 years. As mentioned, the development of cancer is variable and is based in part on the location of the germline mutation in the APC gene. Colon cancer is rather unusual before 30 years of age, and cancer may not develop in patients with the attenuated form of FAP until they are in their 50s or 60s. Cancer occurring in the teenage years has been reported as a result of a patient who had both FAP and Lynch syndrome.⁴¹ Thus, the treatment of these patients relies increasingly on a genetic characterization of the disease.

Extraintestinal Features. Traditionally, patients with manifestations of FAP together with extraintestinal manifestations were considered to have Gardner syndrome. It is now appreciated that families with FAP all have extraintestinal manifestations and that no distinction can be made between families with Gardner syndrome and those with FAP.⁴² FAP is characterized by osteomas of the mandible, skull, and long bones and a variety of other benign soft tissue tumors, such as fibromas, lipomas (Fig. 67.15), and sebaceous cysts, which should not be confused with the sebaceous adenomas and carcinomas seen in the Muir-Torre syndrome variant of Lynch syndrome. Osteomas are commonly found in the skull and may be multiple. Some of these lesions have been reported to regress and later reappear. Osteomas may also be found in the mandible, and radiographs of the mouth may reveal impacted or supernumerary teeth. Congenital hypertrophy of the retinal pigmented epithelium (CHRPE) is present in some families with FAP, depending on the location of the mutation in the APC gene. CHRPE lesions may be seen in the general population but are small and usually single. Multiple, bilateral, and large CHRPE lesions are essentially diagnostic of FAP. It will require a slit lamp examination and knowledgeable ophthalmologist to make this diagnosis with confidence, as these are not readily seen in an office ophthalmoscopic examination.

Malignant tumors in the colon are considered to be nearly inevitable, and they may occur occasionally in the duodenum or (less commonly) elsewhere in the gastrointestinal tract. Patients with FAP are also at increased risk for brain tumors

(particularly medulloblastomas), thyroid tumors, adrenal tumors, and malignant tumors of the hepatobiliary tree. The occurrence of a malignant brain tumor in conjunction with intestinal polyposis was traditionally referred to as *Turcot syndrome*, although this is not a distinctive disease process. Medulloblastomas are a rare complication of FAP, and the risk for this tumor is increased 99-fold in FAP families. Interestingly, one of the index families initially reported by Turcot in 1959 (and several others characterized as Turcot syndrome) did not have FAP, but actually had Lynch syndrome complicated by astrocytomas.¹⁷

Desmoid Tumors. Desmoid tumors are currently the major cause of mortality and morbidity in FAP (after colorectal cancer) and develop in 10% to 15% of such patients, often as a complication of laparotomy, but sometimes spontaneously. These are benign but aggressive tumors of mesenteric fibroblasts that can envelop and obstruct the gastrointestinal tract, arteries, veins, or ureters. They frequently occur in the abdominal wall. In some instances, desmoid tumors can become quite large, may virtually fill the abdominal cavity, and can be lethal. These can be visualized on CT of the abdomen, and surgical management of these should be avoided unless they are superficially located. These are more common in women and in those with a positive family history of desmoid tumors.

Genetic Basis. FAP occurs when a germline mutation in the APC gene inactivates the function of the APC gene product. In most instances, the genetic lesion creates a premature stop codon in the APC gene, which in turn leads, to nonsense-mediated decay of the mRNA or the translation of a truncated, nonfunctional APC protein. The APC gene encodes a large protein (311 kD) that binds to other intracellular proteins—namely, the catenins and E-cadherin.⁵ Depending on the location of the premature stop codon, the mutant protein is of variable length. The APC gene encodes 2843 codons (i.e., one for each amino acid) and is broken into 15 translated exons. The structure of the APC gene is unique in that the 15th exon makes up about 75% of the coding sequences of the gene. Because it is unusually large, this long, open reading frame is a natural target for the types of mutations that result in premature stop codons. This genetic vulnerability probably accounts for the fact that 25% to 33% of mutations in the APC occur de novo, in the absence of a prior family history.

FIGURE 67.15. Extraintestinal manifestations of familial adenomatous polyposis (FAP). **A:** Skull film demonstrating osteomas of the calvarium (arrows). **B:** Photograph of the mandible demonstrating protuberant mandibular osteomas. **C:** Mandibular radiograph demonstrating a large osteoma of the mandible. **D:** Chest radiograph demonstrating multiple fibromas (arrows) in a patient with FAP.

The location of the germline mutation is of some clinical significance (Fig. 67.16). For example, mutations that occur at the 5' end of the gene, particularly in the first three exons, result in a clinically mild or "attenuated" form of FAP, in which the number of polyps is smaller and the onset of disease about 10 years later, with cancer developing in the sixth or seventh decade.⁴³ This occurs because the *APC* gene has a ribosomal reentry site downstream of the mutation, which permits the cell to bypass and ignore the premature stop codon. To complicate the situation, family members with the same mutation may have variable manifestations of the disease. Indeed, some members who inherit this mutation have few polyps and no cancer, yet can pass an increased risk for cancer to their progeny.

In contrast, mutations that occur in the "mutation cluster region" of the 15th exon, in a segment between codons 1250 and 1464, are associated with a particularly virulent form of the disease, in which the number of polyps is greater than 5,000 and the average age for the development of colorectal cancer is significantly earlier (median age, 34 years). Also, mutations at the extreme 3' end of the gene are also associated with a milder phenotype, with fewer polyps, and later onset of cancer.

In families who have FAP with CHRPE lesions, the mutations are almost always in exons 9 to 15 and rarely in families whose mutations are in the first eight exons. Thus, knowledge of the location of the germline mutation can be useful in predicting the clinical manifestations and guide therapy.

5 Diagnosis. The clinical diagnosis of FAP is usually obvious clinically, but the availability of a genetic diagnosis has changed the approach to this disease. Currently, optimal practice is to obtain a germline diagnosis in an individual who is definitely affected, in order to characterize and counsel the family. A mutation in *APC* can be found in most (~90%) of these individuals using commercially available diagnostic laboratories. This will assist in the early and definitive identification of family members who carry the disease-causing mutation and will alleviate anxiety for those who do not. The risk to inherit the mutated gene from an affected parent is 50%, and there is no gender preference. A genetic diagnosis is particularly useful in the attenuated forms of FAP, where the diagnosis is not obvious, and this can help select those family members who need additional surveillance and reassure those who do not.

In some instances, the phenotype indicates FAP, but no mutation can be found in the *APC* gene. In this instance, the relatives at risk should undergo surveillance sigmoidoscopy on an annual basis beginning in their middle teens. If a single adenoma appears in a teenager at risk, the disease is strongly suspected, and the individual should be managed as if he or she is a mutation carrier. Almost no other disease produces multiple adenomatous polyps in young patients.

About 25% of patients have FAP that is not present in either parent. This can represent the autosomal recessive form of the disease (*MYH*-associated polyposis; see later), misattribution

FIGURE 67.16. Peutz-Jeghers syndrome. **A:** Perioral hyperpigmentation. **B:** Hyperpigmented buccal mucosa. **C:** Gross specimen of a Peutz-Jeghers polyp illustrating a large multilobular lesion. **D:** Low-power photomicrograph of a Peutz-Jeghers polyp of the colon revealing smooth muscle stroma covered by nonneoplastic colonic epithelium. **E:** Photomicrograph of the Peutz-Jeghers polyp at higher power indicates that the stroma contains arborizing bands of smooth muscle.

of paternity, or phenotypic variation in which a parent actually has a milder form of the disease.

Genetic testing is an essential part of the clinical management of the hereditary cancer, but it can be a challenge. The genetic results are sometimes ambiguous and difficult for the physician to interpret.⁴⁴ Additionally, some patients mistake the germline test as a test for cancer. Issues of guilt and denial are prominent in genetic disorders. It is strongly recommended that physicians enlist the involvement of genetic counselors when performing genetic testing and counseling in such patients.

Management. Surgery is the only reasonable management option in FAP, and the clinical decision involves the selection

and timing of the operation. The diagnosis of FAP is often made in adolescence, but the development of cancer may not be anticipated for 20 to 30 years after the first polyp appears, depending on the location of the mutation in the *APC* gene. When a child is found to have a germline mutation in *APC*, sigmoidoscopy should begin in the early teenage years, particularly if the mutation is in the “mutation cluster region” or the family’s phenotype is known to be associated with thousands of polyps. Ideally, one would like a patient to reach adulthood prior to the colectomy, as the pelvis is larger and the individual is better able to cope with the disease psychologically.

The safest surgical approach is a total proctocolectomy with an ileoanal pouch anastomosis. No rectal mucosa should be left behind, since it is at risk for the development of neoplasia.

Even with careful endoscopic surveillance of the rectal segment, invasive carcinomas may develop.

The fact that small adenomatous polyps of the rectum can spontaneously regress visibly after a subtotal colectomy and ileorectal anastomosis underscores the reversible nature of the benign adenoma. Additionally, it has been found that adenomas can regress in FAP in response to treatment with sulindac (Clinoril). Several reports have confirmed that even large numbers of polyps regress in patients on 150 to 200 mg of sulindac twice per day.⁴⁵ Unfortunately, the polyps reappear when the drug is stopped, and development of cancer despite treatment with sulindac has been reported. Medical treatment is therefore not a safe or reliable first-line treatment for FAP, but it may be of some benefit in patients who delay operative intervention. Although no data are available to support this approach, sulindac may be a useful adjunct in patients with milder forms of FAP (i.e., smaller numbers of polyps with relative rectal sparing) and in circumstances in which residual rectal tissue must be left behind. Sulindac is not effective in the management of upper gastrointestinal tract neoplasia.

Management of Extracolonic Disease. In addition to the risks for colorectal neoplasia, patients with FAP are at risk for the development of osteomas, lipomas, fibromas, and a variety of other lesions. Although these mesenchymal tumors can degenerate into sarcomas, this is a sufficiently rare event that prophylactic surveillance and surgery are not indicated. Likewise, the CHRPE lesions do not require therapy. Gastric carcinoma is distinctly uncommon in North American populations, and it is not necessary to provide endoscopic surveillance of the stomach. The risk for gastric cancer in FAP is 0.5%.

The two major management issues after removal of the colon and rectum are periampullary neoplasia and desmoid tumors. One or more adenomas are found in the duodenum in 90% of patients with FAP, usually close to the ampulla of Vater. These lesions should be excised for biopsy and destroyed by electrocautery, laser, or other ablative approaches. Subsequent examination of the upper gastrointestinal tract is guided by the Spigelman criteria (Table 67.4).

TABLE 67.4

SPIGELMAN'S CLASSIFICATION FOR MANAGEMENT OF DUODENAL ADENOMAS IN INDIVIDUALS WITH FAP

	■ POINTS		
	■ 1	■ 2	■ 3
A. Duodenal Disease Grading			
Polyp number	1–4	5–20	>20
Polyp size (mm)	1–4	5–20	>20
Histology	Tubular adenoma	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe
B. Recommended Upper GI Surveillance in FAP			
Spigelman stage	Interval to EGD		
Stage 0 (0 points)	5 y		
Stage I (1–4 points)	5 y		
Stage II (5–6 points)	3 y		
Stage III (7–8 points)	1–2 y		
Stage IV (9–12 points)	EUS or surgery		

EGD, esophagogastroduodenoscopy; EUS, endoscopic ultrasound; FAP, familial adenomatous polyposis; GI, gastrointestinal.

Complex neoplasms, including adenomas with varying degrees of dysplasia, may require individualized management, including the use of biliary stents while extensive ablative therapy of the periampullary region is performed. Surgical approaches may be required for advanced neoplasms (i.e., carcinoma in situ or invasive carcinoma), but therapeutic endoscopy remains the first option. Duodenotomy with local surgical excision is an option for these lesions; rarely, a Whipple procedure is required for invasive lesions in this region.

Desmoid tumors are aggressive benign tumors of fibroblasts that can cause multiple clinical complications; they are a significant cause of morbidity and mortality in FAP. They typically grow slowly and can surround or compress vascular structures, nerves, or the abdominal viscera. They are more commonly seen in women and may be hormonally responsive, so estrogen administration (oral contraceptives or hormone replacement therapy) should be avoided in these patients. Surgical management is generally avoided unless simple local excision of an abdominal wall lesion is possible, and postoperative recurrences are common. Radiotherapy has been used to control the growth of some of these but is generally reserved for superficial lesions of the abdominal wall. No medical approach to this disease has been uniformly successful. A combination of sulindac plus tamoxifen may be tried for intra-abdominal tumors and has been successful in some patients. Cytotoxic chemotherapy with doxorubicin was successful in a patient whose tumor was refractory to other treatment. Anecdotally, some of these lesions may have *c-kit* mutations and are responsive to imatinib (Gleevec).

Familial Adenomatous Polyposis Variants. A number of names, especially *Gardner syndrome*, have been attached to variations of FAP to emphasize the presence of particular extracolonic findings. As mentioned, Gardner syndrome is the same entity as FAP. A few families with prominent sebaceous cysts were historically said to have Oldfield syndrome, and families with brain tumors were said to have Turcot syndrome. All these syndromes represent the variable expression of germline mutations in the *APC* gene and are largely of historical interest. The current mode of classifying FAP families is based on the *APC* gene mutation.

MYH-Associated Polyposis

An autosomal recessive form of polyposis has been linked to inheritance of germline mutations in the base excision repair gene *MYH*, a DNA glycolase.⁴⁶ This should be considered when multiple adenomatous polyps occur in siblings or in a person who has no vertical family history of polyposis and there is no detectable germline mutation in the *APC* gene. These patients have a relatively mild (attenuated) form of adenomatous polyposis and will develop 20 to 500 adenomas, and the polyposis is typically detected in patients 35 to 65 years old. These patients are at very high risk for colorectal cancer, and the disease may present with cancer. The extraintestinal manifestations of FAP, such as duodenal adenomas or CHRPE lesions, occasionally occur but are less common in this condition. The pathogenesis of this disease is that the germline mutations in *MYH* permit an excess number of acquired mutations in the *APC* gene to occur in the colon; these mutations are typically G:C → T:A transversions, which is a consequence of losing the DNA base excision repair system. More than 1.3% of the Caucasian population carries single Y179C, G396D, and E480X (previously designated Y165C, G382D, and E466X, respectively, but changed due to renumbering of the coding sequence) mutations, and these carriers have a slight increase in colon cancer risk.⁴⁷ Many reference laboratories are currently testing for the three commonest *MYH* mutations on DNA sent from patients with a diagnosis of FAP if there is no detectable germline mutation (or deletion) in *APC*.

TABLE 67.5**GENETIC ALTERATIONS IN COLONIC POLYPOSIS SYNDROMES**

POLYPOSIS SYNDROME	CHROMOSOME	GENE
Familial adenomatous polyposis (FAP)	5q21 1p35	APC (dominant) MYH (recessive)
Peutz-Jeghers syndrome	19p13.3	LKB1/STK11

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is an autosomal dominant familial syndrome associated with multiple gastrointestinal polyps and characteristic skin pigmentation. The gene responsible for this disease is on chromosome 19p3.3 and encodes a serine/threonine kinase called *LKB1* or *STK11* (Table 67.5); carriers of the gene are highly predisposed to a number of early-onset cancers.

Gastrointestinal Features. The gastrointestinal polyps in Peutz-Jeghers syndrome are nonneoplastic hamartomas consisting of a supportive framework of smooth muscle tissue covered by somewhat hyperplastic epithelium (Fig. 67.16). These are histologically distinct from juvenile polyps and show no inflammatory cell infiltrate. Polyps may be found in the stomach, small intestine, or colon, and in each instance they have a distinctive appearance. Peutz-Jeghers polyps can usually be identified as such by the pathologist, and the characteristic cutaneous pigmentation makes this syndrome readily recognizable.

Skin Lesions. The cutaneous manifestations of Peutz-Jeghers syndrome may be found early in life and consist of dark, macular lesions on the mouth (both on the skin and in the buccal mucosa), nose, lips, hands, feet, genitalia, and anus. These lesions tend to become less obvious by the time of puberty. Unlike ordinary freckles, the cutaneous lesions of Peutz-Jeghers syndrome are present from birth. Moreover, ordinary freckles typically do not extend beyond the vermilion border of the lips, nor is the buccal mucosa involved, as it is in Peutz-Jeghers syndrome.

Clinical Complications. The principal complication of Peutz-Jeghers syndrome is intestinal obstruction, which may develop in infancy or childhood. This complication is most prominent in the small intestine because of its narrower diameter. Gastrointestinal bleeding may also be seen in this disease.

Cancer in the small intestine or colon can occur in Peutz-Jeghers syndrome; however, this is an uncommon complication.⁴⁸ It is thought that neoplasia may arise from foci of adenomatous epithelium found in some Peutz-Jeghers polyps. The risk for cancer is such that prophylactic surgery is not recommended.

Patients with Peutz-Jeghers syndrome are at increased risk for cancers within and outside the gastrointestinal tract. Cancer developed in about half of the patients in one large study at a median age of about 50 years. At risk are the stomach, small intestine, colorectum, gonads, breasts, pancreas, and biliary tree. Ovarian cysts and sex cord tumors are seen in 5% to 12% of female patients, and boys are at risk for endocrinologically active Sertoli cell testicular tumors that may produce feminizing features before puberty. No internal organ is individually at sufficiently high risk for cancer that a specific screening regimen or prophylactic surgery is indicated. The clinician should be aware of these risks, however, and should be particularly alert to gonadal tumors (which are otherwise rare) and breast cancer (for which screening should start at an early age and bilateral disease should be suspected).

Management. The management of Peutz-Jeghers syndrome is limited to the removal of polyps; endoscopic techniques should be used when possible. Surgery may be required for intussusception caused by small-intestinal polyps. The risk for neoplastic development should be kept in mind, but these patients are not candidates for prophylactic removal of any section of the gastrointestinal tract. As mentioned earlier, gonadal neoplasms and breast cancer are potential complications that may require surgery.

Juvenile Polyposis

Juvenile polyps are pathologically characteristic lesions that can be solitary or part of a polyposis syndrome. Juvenile polyps are most commonly solitary lesions found in the rectum during childhood. The lesions may be large and are made up of an edematous, mildly inflamed lamina propria covered by normal colonic epithelium (Fig. 67.17). If multiple polyps are found, a familial juvenile polyposis syndrome should be suspected. Three different syndromic presentations have been reported; it is not known, however, whether these are truly distinctive syndromes. They may consist of familial juvenile polyposis limited to the colon, familial juvenile polyposis throughout the gastrointestinal tract, and familial juvenile polyposis limited to the stomach. The genetic basis of this syndrome is not understood, but germline mutations in the *SMAD4* (also called the *MADH4* gene) and *BMPR1A* genes each account for about 20% of juvenile polyposis cases in which the genetic cause can be found.^{49,50} Both these genes are involved in the TGF- β signaling pathway. Curiously, germline mutations in

FIGURE 67.17. Photomicrograph of a juvenile polyp reveals an attenuated surface epithelium overlying an edematous lamina propria with fluid- and mucus-filled cystic structures.

these same genes can cause hereditary hemorrhagic telangiectasia. Although alterations in the *PTEN* gene had initially been linked to juvenile polyposis, germline mutations in this gene are only found in the rare Bannayan-Riley-Ruvalcaba variant, a childhood disorder characterized by macrocephaly, intestinal polyps, and unique pigmented macules of the penis⁵¹; this disorder shares features with Cowden syndrome, which is also caused by *PTEN* mutations.⁵² Juvenile polyposis is a topic in need of additional clarification at the genetic and clinical levels.

The manifestations of juvenile polyposis can vary but are largely limited to bleeding, intussusception, obstruction, and the passage of autoamputated lesions. In some children, a life-threatening protein-losing enteropathy may develop that requires surgical resection of the affected segment of intestine. Patients with familial juvenile polyposis are at increased risk for the development of colorectal cancer and require careful surveillance.

Other Familial Polyposis Syndromes

A variety of other rare syndromes may give rise to multiple gastrointestinal polyps. Cowden syndrome consists of multiple gastrointestinal hamartomas and may be complicated by multiple lesions of the face that arise from follicular epithelium and are pathologically trichilemmomas.⁵³ The diagnosis of Cowden syndrome should be considered for patients with multiple trichilemmomas. Gastrointestinal polyps, which are usually asymptomatic, may develop in these patients. The polyps may include hamartomas, hyperplastic polyps, and ganglioneuromas of the colon. Glycogenic acanthosis of the esophagus may also occur and usually is found incidentally as multiple, diminutive, flat polyps of the esophagus. These patients are at increased risk for the development of breast cancer, uterine cancer, and thyroid neoplasms. No specific therapy need be directed toward the gastrointestinal tract. Germline mutations of the *PTEN* gene can be identified in most families with Cowden syndrome.⁵⁴

Other diseases, such as neurofibromatosis (von Recklinghausen syndrome) and the basal cell nevus syndrome, may be associated with multiple gastrointestinal polyps; however, symptomatic complications of these polyps are uncommon. Bannayan-Riley-Ruvalcaba syndrome is a generalized hamartoma syndrome inherited in an autosomal dominant manner that is characterized by ileal and colonic polyps and lingual lesions. Other characteristics include ocular abnormalities, delayed motor development, lipid storage myopathy, and Hashimoto disease. This disease is most often linked to germline mutations in the *PTEN* gene.

NONFAMILIAL GASTROINTESTINAL POLYPOSIS SYNDROMES

Multiple gastrointestinal polyps are occasionally seen in non-familial syndromes. The Cronkhite-Canada syndrome is an acquired, nonfamilial syndrome characterized by cutaneous lesions (Fig. 67.18), chronic diarrhea, protein-losing enteropathy, and gastrointestinal polyps. The enteropathy may produce progressive inanition that can result in death. The diarrhea is attributable to diffuse mucosal injury of the small intestine but may be complicated by bacterial overgrowth. Gastrointestinal polyps are present in most patients and occur in the stomach, small intestine, colon, and rectum. These polyps are pathologically similar to juvenile retention-type polyps. The lamina propria is edematous and contains an inflammatory infiltrate. As has been reported in juvenile polyps, the lesions in this syndrome may contain adenomatous epithelium, and occasionally

FIGURE 67.18. Cronkhite-Canada syndrome. Onycholysis and hyperpigmentation are characteristic cutaneous manifestations of Cronkhite-Canada syndrome, a nonfamilial, poorly understood, and acquired condition in which multiple juvenile, inflammatory-type gastrointestinal polyps and characteristic cutaneous features are found.

carcinomas have complicated this disease. A variety of medical and surgical measures have been used as treatment, and primary attention should be drawn to the treatment of the diarrhea and maintenance of the nutritional status. The cutaneous lesions consist of onycholysis, alopecia, and hyperpigmentation. Multiple therapeutic approaches have been tried, including broad-spectrum antibiotics, steroids, antihistamines, and extended bowel rest with parenteral nutritional support. Each approach has had occasional success, but none is uniformly effective. Curiously, the cutaneous features may resolve despite persistence of the gastrointestinal polyps.

Other acquired lesions that may present with multiple gastrointestinal polyps include inflammatory pseudopolyps in the setting of inflammatory bowel disease, lymphoma, pneumatosis cystoides intestinalis, and multiple lipomas or hyperplastic polyps. None of these syndromes requires specific surgical treatment.

CHAPTER 68 ■ COLORECTAL CANCER

ARDEN MORRIS

KEY POINTS

- 1 Epidemiologic studies have suggested that 15% of colorectal cancers occur in a dominantly inherited pattern. The two best-described familial colorectal cancer syndromes are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). Currently, it is estimated that 5% of all colorectal cancers occur in persons affected with one of these two syndromes.
- 2 Mutations in three distinct types of genes are known to contribute to colorectal cancer formation: oncogenes, tumor-suppressor genes, and DNA mismatch repair genes. The former two mechanisms, comprising the loss of het-

erozygosity or chromosomal instability pathway, account for about 85% of colon and rectal tumors. Mutations in mismatch repair genes, termed the replication error or microsatellite instability pathway, account for about 15% of large bowel tumors.

- 3 The incidence of invasive malignancy differs markedly for the three histologic subtypes of colon polyps, being lowest in adenomatous polyps, intermediate in tubulovillous adenomas, and highest in villous lesions. Polyp size is directly correlated with the presence of dysplasia or malignancy.

- 4 The most important prognostic factor in colorectal cancer is dissemination to nearby lymph nodes or distant organs.
- 5 The surgical goals in the resection of a primary colorectal cancer are to achieve an en bloc resection that encompasses an adequate amount of normal colon proximal and distal

to the tumor, to obtain adequate lateral margins if the tumor is adherent to contiguous structures, and to remove the regional lymph node basin.

- 6 The liver is the most frequent site of blood-borne metastases from primary colorectal cancers.

Adenocarcinoma of the large intestine is the fourth most common malignancy in the United States, with an estimated incidence of 146,970 new cases in 2009.¹ Colorectal cancer is second only to lung cancer as a cause of cancer-related deaths. In 2009, an estimated 49,920 persons died of colorectal cancer in the United States. If diagnosed in its early stages, however, colorectal cancer is one of the most curable malignancies. Most early-stage colorectal cancer is curable by surgical treatment. Because of the potential for surgical cure of early-stage or localized disease, identification of populations at risk and screening of asymptomatic patients are important considerations. For regional disease, controlled clinical trials have demonstrated that a multidisciplinary approach can reduce cancer-specific mortality substantially² (Fig. 68.1). For recurrent disease, various therapeutic approaches are reviewed. Other colorectal tumors distinct from adenocarcinoma, such as lymphomas, sarcomas, gastrointestinal stromal tumors, and carcinoid tumors, are discussed at the end of the chapter.

EPIDEMIOLOGY

Incidence and Mortality

Worldwide, colorectal cancer is the third most common cancer in men and the fourth most common cancer in women. An

important feature of colorectal cancer is the wide variation in incidence (as much as 30-fold) noted between population groups according to geographic region (Fig. 68.2). Although industrialized countries such as those in Northern and Western Europe have the highest incidence rates, these trends are stable or actually decreasing. In contrast, the incidence of colorectal cancer is increasing notably among economically transitioning areas, such as Eastern Europe, most of Asia, and several parts of South America.³ These geographic differences cannot be attributed solely to genetic factors for several reasons. First, populations migrating from low- to high-incidence regions can experience an increase in the incidence of colorectal cancer within a single generation.⁴⁻⁶ Second, even among nonmigrants, incidence rates can change with in-country lifestyle trends. In some parts of Japan, a highly industrialized country, the incidence of new colorectal cancers among men has increased by more than 90%, concurrent with Westernization of the regional diet.³ These data provide indirect evidence that environmental factors, including diet and lifestyle, are involved in the pathogenesis of this disease—thus, its incidence may be reducible.

In the United States, the incidence of colorectal cancer overall has been in decline since 1992, with a current lifetime incidence risk of just over 5%.¹ This phenomenon is largely attributed to improvements in screening, during which precancerous polyps are detected and removed. The declining incidence of

Leading Sites of New Cancer Cases and Deaths – 2010 Estimates

FIGURE 68.1. Leading sites of new cancer cases and deaths in the United States, 2010. (American Cancer Society. *Cancer Facts & Figures 2010*. Atlanta: American Cancer Society; 2010.)

FIGURE 68.2. Incidence of colorectal cancer per 100,000 persons in 23 geographic regions during 1980. (Adapted from Parkin DM, Laara E, Muir CS. Estimates of the worldwide frequency of sixteen major cancers in 1980. *Int J Cancer* 1988;41: 184.)

colorectal cancer has been slower among African Americans compared with whites. Among African American men, the colorectal cancer incidence rate is 21% higher than among white men. Among African American women, the incidence rate is 26% higher than among white women. In contrast, among Hispanic men and women the incidence rate is about 25% lower than among their white counterparts.

In 2005, the overall survival rate of colorectal cancer was 66% among whites compared with 55% among African Americans. Overall survival has improved significantly for whites and African Americans over the past 10 years, although the survival gap between groups has widened.⁷ Higher colorectal cancer-specific mortality among African Americans is attributed to differences in systematic high-quality screening and in appropriate treatment, rather than to modifiable lifestyle factors (such as smoking) or differences in tumor biology. This important distinction underscores the necessity of addressing barriers to healthcare access and barriers to care within the healthcare system.

Modifiable Risk Factors

Dietary Factors. In North America, colorectal cancer tends to be more prevalent in urban populations and among people of higher socioeconomic status. Although there is no evidence of a geographic carcinogenic agent or high-risk occupational exposures,⁸ several possible risk factors have been identified that may be linked to modifiable behaviors.

① Epidemiologic studies suggest that dietary factors play causative and protective roles in the development of large-bowel cancers.⁹ Red meat and fat intake have the most consistently direct association, and fiber intake has the most consistently inverse association with colorectal cancer (Fig. 68.3). For example, in comparisons between countries, the associations between per capita consumption of total fat, saturated fat, and cholesterol and the national incidence rates of colon cancer are strongly positive.¹⁰ However, whether the responsible mechanism is interaction with bile acids or simply excess fuel consumption and resultant obesity is controversial.^{9,11}

In industrialized countries, red meat intake is associated with elevated long-term risk of cancer primarily in the distal colon.^{12–14} Several mutagenic compounds in cooked meat have been identified including heterocyclic amines. The site-specific nature of fat- and meat-associated tumorigenesis may be due to the relatively slower transit time and narrowed lumen of the distal colon resulting in prolonged toxin exposure.

The inverse association between intake of fiber (the nondigestible component of cereal products, vegetables, and fruit) and colon cancer was initially noted by Burkitt,¹⁵ who reported low rates of colon cancer in areas of Africa with high fiber consumption. The role of fiber was originally seen simply as the provision of bulk to dilute potential carcinogens and speed their transit through the colon. However, dietary fiber comprises a diverse collection of carbohydrates that are unlikely to have identical physiologic effects. Reflecting the heterogeneous nature of fiber, data now suggest that the relationship between fiber intake and colon cancer is more complex. Certain fibers

FIGURE 68.3. Correlation between meat intake and the incidence of colon cancer among women in 23 countries. (Adapted from Willett W. The search for the causes of breast and colon cancer. *Nature* 1989;338: 389.)

can bind mutagens, reducing their contact with colonic epithelium; others can favorably change the fecal pH or participate in other complex interactions.

Although the protective role of fiber is incompletely defined, recent evidence indicates a potential 20% to 50% risk reduction, particularly noted among frequent consumers of dark green vegetables.^{9,11,12} Preliminary data suggest that micronutrients such as folate, methionine, vitamin D, and calcium may provide protection against oxidative stress at the cellular level. Whether the protective effect of leafy green vegetables is due primarily to mechanical effects of fiber or to a chemoprotective effect of micronutrients remains unknown.

Alcohol Consumption. A positive dose response effect of alcohol on colorectal cancer formation has been extensively demonstrated. Beer apparently plays a more important role in mucosal neoplasm formation than wine or spirits.¹⁶ Although the mechanism of mutagenesis has not been determined, the metabolite acetaldehyde is generally considered the culprit. Acetaldehyde may contribute to free radical formation and proliferative growth of mucosal polyps. Folate and calcium appear to have a protective effect, possibly by competing with aldehyde for binding sites at the mucosal surface. These hypotheses are supported by decreased colorectal cancer rates seen among heavy drinkers who consume large quantities of dietary folate, for example in leafy greens, coupled with higher colorectal cancer rates among drinkers with a low intake of leafy green vegetables.

Smoking. After much dissent in the literature, a recent meta-analysis¹⁷ of 106 observational studies has demonstrated 18% higher odds of developing colorectal cancers (CRC) among ever-smokers compared with never-smokers. Risk was significant only among persons who smoked more than 30 years and was dose dependent. The association between cigarette smoking and cancer mortality was even stronger. That is, ever-smokers were 25% more likely to die of colon cancer causes than never-smokers. For unknown reasons, risk was markedly higher for cancers in the rectum compared with those in the colon.

Exercise and Obesity. The cancer prevention benefits of regular exercise have been increasingly recognized for colon (not rectal) cancer. Although the mechanism of action remains unclear, exercise is thought to reduce inflammation and potentially contribute to reduced free radicals. In a pooled analysis of 19 studies, men and women who averaged more than 4 hours per week of moderate exercise demonstrated a 22% and 29% reduction in CRC incidence, respectively.¹⁸ In addition, regular exercise reduces obesity, which is also associated with colorectal cancer incidence. Obesity may contribute to colon cancer formation via fat metabolism pathways or hyperinsulinemia. Notably, central obesity (waist circumference) has an even more robust association with increased colorectal cancer incidence than body mass index.^{19,20}

Clinical Risk Factors

Familial Cancer Syndromes. Although up to 30% of persons diagnosed with colorectal cancer have some family history, the vast majority of colorectal cancer cases have no apparent familial association and therefore are considered sporadic. Epidemiologic studies have suggested that at least 15% of all colorectal cancers occur in a dominantly inherited pattern, and that an inherited susceptibility to polyps and cancer could account for up to 90% of the total number of colorectal cancers in the population.^{21,22} The two best-described familial colorectal cancer syndromes are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC). Currently, it is estimated that 5% of all colorectal cancers occur in persons affected with one of these two syndromes (Table 68.1).

Breast or genital tract cancer
GENERAL
Age >40 years
Family history of colorectal cancer

FAP is an autosomal, dominantly inherited disease caused by mutations in the APC gene. In affected subjects, hundreds to thousands of adenomatous polyps typically develop throughout the colon and rectum, each of which has the potential to progress to an invasive cancer. The average age for the diagnosis of colorectal cancer is 42 years, markedly earlier than the average age of 63 years in sporadic cases. Cancer develops in virtually all affected persons by age 55. Polyps are also found in other regions of the gastrointestinal tract in patients with FAP, especially the duodenum and stomach. Duodenal and perampullary polyps in particular are at increased risk of malignant transformation.^{23,24} Additionally, several extraintestinal manifestations of FAP have been described, including congenital hypertrophy of the retinal pigment epithelium (CHRPE), osteomas, and desmoid tumors. This and other polyposis syndromes are discussed in more detail in Chapter 67.

HNPCC kindreds were first described in 1913 by Aldred Warthin, a pathologist at the University of Michigan. One kindred, referred to as family G, has been followed extensively through the years and represents a classic example of the HNPCC syndrome.^{25,26} A more systematic collection of families and analysis of their pedigrees was performed by Henry Lynch et al. at Creighton University. Although colorectal cancers in this syndrome derive from adenomatous polyps, an associated polyposis phenotype is absent. Thus, the syndrome was given the nonpolyposis designation. Two phenotypic variants of HNPCC have been described: Lynch syndromes I and II. Lynch syndrome I families manifest only colon cancer. Lynch syndrome II families manifest colon cancer in addition to several others, including endometrial, ovarian, gastric, small-bowel, liver and biliary tract, upper urologic tract, and central nervous system cancers. The median age for the development of either colorectal or endometrial cancer in HNPCC patients is 39 to 46 years.²⁷ HNPCC occurs in about 1 to 2/1,000 individuals, and its penetrance is estimated at 70% to 90% for colon cancer. An unusual clinical variant of HNPCC is the Muir-Torre syndrome, in which affected members have sebaceous tumors (both benign and malignant) and keratoacanthomas in addition to the spectrum of tumors found in Lynch syndrome II.

The clinical criteria necessary for identifying a family as an HNPCC kindred were established initially by an international collaborative conference in Amsterdam in 1990. The Amsterdam criteria are based on exclusion of FAP and a 3-2-1 rule: (i) at least *three* relatives with histologically verified colorectal cancer, with at least one being a first-degree relative of the other two; (ii) at least *two* successive generations affected; and (iii) diagnosis of colorectal cancer in *one* of the relatives before the age of 50 years.²⁸ With further study of HNPCC kindreds, the Amsterdam criteria were revised as Amsterdam II, to include at least three relatives with HNPCC-associated cancers in lieu of colorectal cancers only.²⁹ However, a proportion of individuals at risk for HNPCC still do not satisfy the Amsterdam II criteria.³⁰ To better guide recommendations for genetic evaluation, the Bethesda criteria were developed and recently revised as an alternative system for identifying HNPCC kindreds (Table 68.2).^{31,32} Although these criteria schemes provide acceptable capture of patients, test characteristics and ease of use differ. The tumors of patients in families who satisfy Amsterdam II or the revised Bethesda criteria should be tested for microsatellite instability. A positive result includes presence of at least two of five mismatch repair proteins (mononucleotide markers BAT25, BAT26, D2S123, D5S346, D17S250), and indicates further germline analysis for MSH2/MLH1 germline repair gene abnormalities.³³

Currently, about 40% of familial clusters of colorectal cancer do not have discernable microsatellite instability in their tumors or germline mutations.³⁴ It is plausible that several predisposing hereditary defects will be identified in the future. Therefore, obtaining a thorough family history is mandatory in the workup of any patient with cancer, especially those with onset at a young age or with multiple tumors.

The easy availability of genetic testing by many commercial laboratories has been problematic, as most physicians are not prepared to interpret the results or to counsel patients regarding their cancer risk and treatment. In a study of patients undergoing genetic testing for familial polyposis by a commercial company, it was found that only 19% of patients received genetic counseling before the test, and in 32% of cases, the physician ordering the test misinterpreted the results.³⁵ Although most problems with misinterpretation are encountered with negative results, the interpretation of a positive result also can be difficult. It must be emphasized that a negative result can provide reassurance only if the predisposing mutation in the family is already known. Otherwise, a negative result may mean that the mutation was missed, that it occurred in a promoter or intronic sequence not evaluated, or that a cancer predisposition still exists because of a mutation in another known or unknown disease gene.³⁶ In the case of a positive result, one must be sure that the mutation does in fact confer a cancer risk and that it is not merely a benign polymorphism. Therefore, when identified, patients suspected of having an inherited cancer syndrome should be offered counseling by a cancer geneticist or experienced genetic counselor, both before the test is ordered and after the results are known.

Inflammatory Bowel Disease. A strong association exists between inflammatory bowel disease (IBD) and bowel cancer. For patients with ulcerative colitis, the incidence of malignancy is proportional to the extent of colonic involvement, age at onset, and severity and duration of disease. The duration of inflammatory bowel disease is a critical factor in predicting the likelihood of adenocarcinoma. Cancer develops in about 3% of patients during the first 10 years after the onset of colitis and in an additional 20% during each of the next two decades. The cure rate in patients with ulcerative colitis who are treated for cancer is similar to that in noncolitic patients treated for cancer.³⁷

Patients with Crohn disease are also at increased risk for colon cancer in addition to small-bowel cancer. The risk for malignancy is lower than that reported for ulcerative colitis.

Like the cancers associated with ulcerative colitis, the cancers associated with Crohn disease tend to occur at an earlier age than those in patients without inflammatory bowel disease.

Carcinogenesis in IBD has been garnering attention recently as a novel model of inflammation-induced cancer.³⁸ A key molecule in this process is NF- κ B, a molecule required for expressing proinflammatory cytokines such as reactive nitrogen and oxygen species, which in turn are likely to stimulate growth of neoplastic epithelium or dysplasia. In chronically inflamed or colitic patients, dysplasia is believed to progress from inflammation, to low-grade, to indefinite, to high-grade dysplasia. The lesions are often flat and therefore may be more difficult to detect by colonoscopy or other traditional diagnostic methods.

Polyps. Traditionally, colorectal polyps have been divided into two broad categories: neoplastic and nonneoplastic. Nonneoplastic polyps included hyperplastic, inflammatory, juvenile, and hamartomatous polyps, none of which were considered precursors to colorectal cancer. Neoplastic polyps were adenomas and had the potential to develop into malignant cancers. The incidence of colorectal malignancy is two to five times higher in patients with adenomatous polyps than in those without them. Carcinoma is twice as likely to develop in patients with multiple polyps as in patients with a single polyp. Evidence suggests the existence of a common inherited susceptibility toward both sporadic colonic adenomatous polyps and colorectal cancer.²¹

Adenoma histology can be classified as tubular (75%–100% tubular components), tubulovillous (25%–75% villous components), or villous (75%–100% villous components). Tubular adenomas, or adenomatous polyps, are the most common type and constitute about 75% of neoplastic polyps³⁹ (Table 68.3). Tubulovillous adenomas account for 15% and purely villous adenomas for 10% of neoplastic polyps. All adenomas contain some degree of dysplasia or cellular atypia, which can be graded from mild to severe. Carcinoma in situ and severe dysplasia have been grouped together under the classification of high-grade dysplasia. In contrast to invasive carcinoma, carcinoma in situ has not invaded the muscularis mucosa (Fig. 68.4). The incidence of invasive malignancy differs markedly for the three histologic subtypes. In general, malignancies are

FIGURE 68.4. Anatomic distinction between carcinoma in situ and invasive malignancy in a pedunculated (A) and a sessile (B) adenomatous polyp. Carcinoma in situ is characterized by the absence of invasion into the muscularis mucosae.

DIAGNOSIS

COMPARISON OF CLINICAL CRITERIA FOR HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC)^a

	■ CRITERIA	■ SENSITIVITY ¹⁰⁹	■ SPECIFICITY ¹⁰⁹	■ STRENGTHS	■ WEAKNESSES
AMSTERDAM ^{2,8}	Three relatives with colorectal cancer, meeting all of the following criteria: (i) one of whom is a first-degree relative of the other two; (ii) colorectal cancer in at least two generations; (iii) one or more colorectal cancer cases diagnosed before age 50 years	61 %	67 %	Easy to remember and apply; good specificity	Limited sensitivity
AMSTERDAM II ²⁹	Three relatives with HNPCC-associated cancer; ^b meeting all of the following criteria: (i) one of whom is a first-degree relative of the other two; (ii) colorectal cancer in at least two generations; (iii) one or more colorectal cancer cases diagnosed before age 50 years	78 %	61 %	Easy to remember and apply; good specificity	Improved but limited sensitivity
BETHESDA GUIDELINES ³¹	Meeting any of the following criteria: ^c (i) subjects with cancer in families that fulfill Amsterdam criteria; (ii) subjects with two HNPCC-related cancers; (iii) subjects with colorectal cancer and a first-degree relative with HNPCC-related cancer and/or colorectal adenoma; one of the cancers diagnosed at age <45 years and the adenoma diagnosed at age <40 years	94 %	49 %	Increased sensitivity	Complexity in the clinical setting
REVISED BETHESDA GUIDELINES ³²	Meeting any of the following criteria: (i) colorectal cancer diagnosed in a patient younger than age 50 years; (ii) presence of synchronous or metachronous HNPCC-associated tumors, regardless of age; (iii) colorectal cancer with microsatellite instability high histology in a patient younger than age 60 years; (iv) colorectal cancer in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers diagnosed at age younger than 50 years; or (v) colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-associated tumors, regardless of age			Easier to apply in the clinical setting	Due to recent development, limited data regarding test

^aAfter exclusion of familial adenomatous polyposis.^bHNPCC-associated cancers are colorectal, endometrial, ovarian, stomach, small intestine, biliary tract, ureter, renal pelvis, and brain cancers, and sebaceous gland adenomas and keratoacanthomas in Muir-Torre syndrome.^cFour additional original Bethesda criteria did not increase the sensitivity, but their inclusion decreased the specificity to 25 %: (iv) Subjects with colorectal cancer or endometrial cancer at age <45 years; (v) subjects with right-sided colorectal cancer with an undifferentiated histopathologic pattern diagnosed at age <45 years; (vi) subjects with signet-ring cell type colorectal cancer diagnosed at age <45 years; (vii) subjects with adenomas diagnosed at age <40 years.

TABLE 68.3**NEOPLASTIC COLORECTAL POLYPS**

■ TYPE	■ HISTOLOGIC FEATURES	■ INCIDENCE (%)	■ INVASIVE MALIGNANCY (%)
Adenomatous (tabular adenoma)	Branching tubules embedded in lamina propria	75	5
Villous (villous adenoma)	Finger-like projections of epithelium over lamina propria	10	40
Intermediate (tubulovillous adenoma)	Mixture of adenomatous and villous patterns	15	22

seen in 5% of adenomatous polyps, in 22% of tubulovillous adenomas, and in 40% of villous lesions. Although villous lesions are much less common, they are more likely to harbor a malignancy.

Polyp size is also directly correlated with the presence of dysplasia or malignancy.⁴⁰ Polyps of size greater than 10 mm have long been considered high risk, harboring invasive carcinoma in about 3% of cases. Polyps of size less than 5 mm are considered to be diminutive, with 0 to 0.05% frequency of carcinoma based on extremely large cohort studies.^{41,42} Polyps of size 6 to 9 mm may harbor dysplasia or malignancy, but there is no definitive agreement regarding the benefit-to-risk ratio associated with their removal. Recent reviews have demonstrated 3% of such polyps to have severe dysplasia, but only 0.05% to 0.15% contain invasive cancer.^{42,43}

An additional histologic family of neoplastic polyps, the serrated polyps, have been recognized more recently.⁴⁴ Serrated polyps include hyperplastic-like polyps, mixed polyps (part hyperplastic, part dysplastic), and serrated adenomas. The serrated polyps appear to be susceptible to or initiated by inactivation of MLH1 by methylation, which in turn is thought to initiate rapid acquisition of microsatellite DNA instability. In contrast to most hyperplastic polyps, which are seen in the distal colon, the serrated hyperplastic-like polyps are found in the proximal colon. Other clinical features include higher prevalence among women and older patients, rapid growth, and large size at diagnosis, all of which are also associated with proximal colon cancer. Although this alternative pathway to colorectal cancer is not universally accepted, supportive data include (i) the frequency of sporadic MSI high cancers but paucity of MSI high adenomatous polyps (except in HNPCC), (ii) loss of expression of MLH1 but not MSH2 among both serrated polyps and sporadic MSI high cancers, and (iii) the natural history of hyperplastic polyposis and associated prevalence of right-sided colon cancer.⁴⁴⁻⁴⁷

carcinogen) and by those that alter promotional factors long after the administration of an initiating agent.

As described previously, the human diet contains a myriad of naturally occurring mutagens or substances that can be metabolized into mutagens. A wide range of such substances are generated from interactions between the diet, microbial flora, and colonic mucosal enzymes. In addition, protective mechanisms are present throughout the mucosa to detoxify these compounds. The action of carcinogens on DNA appears not to be an entirely random process. Mutagens typically alkylate DNA at specific carbon residues and cause nucleotide misreading during the next cycle of DNA replication. A mutation commonly seen early in colonic carcinogenesis results in activation of the ras protooncogene, one of several genetic events presumed to occur during malignant transformation.⁴⁸ The activation of ras may be involved in the initiation or promotion of carcinogenesis. Because of the ubiquitous presence of mutagens in the gut, many strategies that aim to reduce colon cancer attempt to interfere with the interaction between mutagens and the target colonic cells.

In animal studies, for example, the role of fat in the pathogenesis of colon cancer appears to be that of a promotional factor. With increasing fat intake, total fecal bile acid increases significantly. Available data suggest that bile acids stimulate the generation of reactive oxygen metabolites that enhance the conversion of unsaturated fatty acids to compounds that promote cellular proliferation. Theoretically, this would facilitate the emergence of a mutated clone of neoplastic cells. Enhanced proliferation of these transformed cells can either compress the time required for carcinogenesis or, perhaps, make the process more efficient. An extension of this concept is the observation that increased dietary calcium has been associated with a decreased risk for colorectal cancer. Experimental data demonstrate that an increase in dietary calcium tends to inhibit colonic proliferative indices, potentially by binding bile acid salts.

ETIOLOGY

Mutagenesis

Carcinogenesis in the colon and rectum has been described in terms of an initiation–promotion model based on experimental observations in laboratory animals. According to this simplified model, the first step involves initiating factors that directly interact with cellular DNA to induce mutations in the genome. Afterward, the process is driven by promotional factors, which are not mutagenic by themselves but enhance cellular proliferation of previously mutated cells. One can enhance or reduce tumorigenesis in experimental animals both by maneuvers that modify the generation of a mutagen (or

Molecular Genetics

The molecular genetic events that lead to colorectal cancer have served as a paradigm for the multiple-step process of tumorigenesis. This concept arose from frequently clinical and pathologic observations of an orderly progression of cellular transformation from normal colonic or rectal epithelium to small adenoma, then to large adenoma, and finally to carcinoma. Identification of these distinct stages has allowed scientists to elucidate the genetic alterations that may be responsible for the progression of the neoplastic process. Coincident with this line of investigation was the discovery of the genetic basis of several familial cancer syndromes in which colorectal cancer is a prominent feature of the phenotype. Taken together, the evidence

FIGURE 68.5. Model of genetic events mediating neoplastic progression in the colon. LOH, loss of heterozygosity.

2 suggests that colorectal cancers result from a series of genetic alterations leading to progressive disordering of the normal mechanisms that control cellular growth and differentiation (Fig. 68.5). It must be noted that not every colorectal tumor will acquire each of the mutations described. Furthermore, other genetic events are likely necessary for cancer formation, and each tumor may have a unique genetic profile. Although simplistic, the current model of multiple-step tumorigenesis facilitates understanding the complex molecular genetics of cancer. Within this paradigm, mutations in three distinct types of genes are known to contribute to colorectal cancer formation: oncogenes, tumor-suppressor genes, and DNA mismatch repair genes. The former two gene mutations, comprising the loss of heterozygosity or chromosomal instability pathway, account for about 85% of colon and rectal tumors. Mutations in mismatch repair genes, termed the replication error or microsatellite instability pathway, account for about 15% of large-bowel tumors. Whereas more than half of these mutations are acquired, the remaining ones appear to be inherited.

In colon cancer, the most important genetic alteration is a mutation of the *K-ras* protooncogene, which is associated with poorer prognosis.⁴⁹ The *ras* protooncogenes are a family of normal genes (*N-ras*, *H-ras*, and *K-ras*) that are highly conserved in nature and encode the production of guanosine triphosphate-binding proteins (G proteins), which are important for signal transduction. G proteins are involved in the transduction of proliferative signals induced by growth factors or factors involved in cell differentiation. The product of a mutated *ras* gene is an abnormal G protein that becomes constitutively activated and continuously stimulates autonomous cell growth. Experimentally, transfection of normal fibroblasts by mutated *ras* genes confers neoplastic properties to those cells.

About half of colorectal carcinomas and a similar percentage of adenomas larger than 1 cm in diameter have been found to have the *ras* gene mutation.^{48,50} By contrast, fewer than 10% of adenomas smaller than 1 cm have this mutation. The *ras* gene mutation may be the initiating event in some colorectal carcinomas or, alternatively, may promote the clonal expansion of a mutated cell population. It appears that the *ras* gene mutation alone is not responsible for tumorigenesis. Other molecular events are required in addition to *ras* gene mutations.

The concept of tumor-suppressor genes arose from several observations. Cytogenetic studies demonstrated that tumor cells often have losses of specific chromosomal regions and suggested that loss of a particular gene or genes could contribute to tumor formation and progression. Conversely, experimental evidence documented that replacement of specific chromosomes or portions of chromosomes in tumor cells could result

in inhibition of growth. It was thus deduced that genes exist that function to keep cellular growth and proliferation in check, and that their loss results in unregulated growth and neoplastic transformation. One such tumor-suppressor gene associated with colon cancer is the *APC* (adenomatous polyposis coli) gene, mutations in which result in the familial cancer syndrome, familial adenomatous polyposis (FAP). In persons affected with FAP, hundreds to thousands of colorectal adenomatous polyps develop, all of which have the potential to progress to a cancer. The lifetime risk for the development of colon cancer is virtually 100%.⁵¹ When linkage analysis was performed in families with FAP, *APC* was mapped to chromosome 5q21 and was subsequently cloned by several groups.^{52,53} The *APC* gene encodes a large protein of 2,843 amino acids that contains several functional domains. A key function of the protein is to bind and thereby decrease intracellular levels of β -catenin. Mutations of *APC* that result in loss of this binding function lead to an increase in free β -catenin, which then activates the expression of other genes involved in cellular growth.^{54,55}

Mutations of *APC* are also commonly found in sporadic cases of colorectal cancer. Approximately 70% of all sporadic cases of colorectal cancer have such mutations. Among those cancers in which *APC* is not mutated, a number have mutations in β -catenin that disrupt its ability to bind to the *APC* protein, and as such, they are phenotypically similar to those in which *APC* is mutated.^{55,56} Mutations in *APC* appear to be an early or initiating event in sporadic colorectal cancer, as mutations in the gene have been identified in aberrant crypt foci, one of the earliest events in the neoplastic proliferation of colonic mucosa.⁵⁷

Mutation or loss of the *p53* tumor-suppressor gene, located on chromosome 17p, is another common genetic event in colorectal cancer. Although *p53* mutations have been found in 75% of sporadic colorectal cancers, they are seen infrequently in earlier lesions, which suggests that inactivation of *p53* is an important event in the transition from adenoma to carcinoma. The *p53* gene codes for a 393-amino acid phosphoprotein that has the ability to bind to DNA in a sequence-specific manner. When bound to DNA, the *p53* protein can activate the expression of certain genes that are presumed to participate in growth inhibition. Mutations that disrupt this ability to bind DNA result in a decrease in the expression of growth-inhibitory genes and an increase in cellular proliferation.⁵⁸ Germline mutations in *p53* are responsible for the Li-Fraumeni syndrome. It is interesting that colorectal cancer is not a prominent feature of the phenotype.

Chromosome 18q21 appears to have an important role in the development of colorectal cancer, as allelic loss of this region

is observed in many cases. The clinical importance of such a loss is controversial; one report has identified 18q21 allelic loss as an independent negative prognostic factor in patients with stage II tumors, whereas others have failed to identify such an association.^{59,60} Several candidate tumor-suppressor genes have been identified on chromosome 18q21, including deleted in colon cancer (*DCC*), deleted in pancreatic cancer locus 4 (*DPC4*) and mad-related (*smad2*) genes. The role of these genes and others in the 18q21 region in colorectal tumorigenesis is not well defined. Investigation has been hampered by the inability to identify a significant number of mutations in any of these genes in sporadic colon cancers and by the lack of any familial syndromes in which germline mutations can be identified.

Similar to the suppressor pathway described previously and characterized by mutations in oncogenes and tumor-suppressor genes, a second and distinct molecular pathway has been implicated in colorectal tumorigenesis. This second pathway is called the mutator or microsatellite instability (*MSI*) pathway. The *MSI* pathway involves disruption of the normal surveillance for and repair of DNA damage. Maintaining the fidelity of the genome during DNA replication and cell division is of paramount importance for the normal growth and development of an organism. Ordinarily, cells have numerous mechanisms that constantly survey DNA for damage or replication errors and, if present, repair them. In this manner, the integrity of the genome is ensured and the accumulation and propagation of mutations is minimized. If these survey and repair mechanisms are defective, genetic instability and accelerated rates of mutation follow. If such mutations result in the activation of oncogenes or the inactivation of tumor-suppressor genes, affected cells gain a growth advantage.

In the early 1990s, several investigators observed that a subset of colorectal tumors have widespread instability in microsatellite repeats in tumor DNA and that such instability is present in the tumors of many patients affected by familial non-polyposis colorectal cancer (*HNPCC*).^{61–63} Simultaneously, bacterial and yeast geneticists described a set of DNA repair enzymes, termed DNA mismatch repair enzymes, that function to excise and repair nucleotide base mismatches that occur during DNA replication. The connection between DNA mismatch repair enzymes and *HNPCC* was solidified when it was found that tumor cells from patients with *HNPCC* lack DNA mismatch repair activity in vitro.⁶⁴ Subsequently, the first human mismatch repair homologue, *hMSH2*, was cloned and was found to be mutated in many patients with *HNPCC*.^{65,66} Soon thereafter, a second human homologue of a mismatch repair enzyme, *hMLH1*, was cloned and demonstrated to be altered in a subset of patients with *HNPCC* who had normal *hMSH2*.^{67,68}

It is now understood that DNA mismatch repair in the eukaryotic cell requires the participation of at least four other enzymes: *hPMS1*, *hPMS2*, *hMSH6* (formerly called *GTBP*), and *hMSH3*.⁶⁹ Together, these enzymes form two complexes that perform the many aspects of the DNA mismatch repair process. Single base pair insertions or errors are recognized by a *MSH2-MSH6* heteroduplex, which then binds a *MLH1-PMS2* heteroduplex to initiate DNA excision. Similarly, larger DNA insertion or deletion loops are recognized by a *MSH2-MSH3* heteroduplex, which again binds a *MLH1-PMS2* heteroduplex and initiates DNA excision.^{70,71} It follows that *hMSH2* or *hMLH1* mutator phenotypes result in the highest microsatellite instability and account for more than 60% of the mutations found in *HNPCC* kindreds. In addition to the germline inactivation of mismatch repair genes seen in *HNPCC*, spontaneous development of *MSI* high tumors results from hypermethylation of the promoter region of *MLH1*.

Delineation of the molecular genetic alterations responsible for colorectal tumor development has defined much of our current understanding of the multiple-step process of tumorigenesis. Yet despite these discoveries, an even greater number of questions remain to be answered. For example, among individuals who carry mutations in the *APC* gene, there is a wide

variability in the phenotype; those affected with mutations that preserve the β -catenin binding domain may manifest a much more attenuated, or even absent, polyposis phenotype with substantially later and less aggressive tumor presentation. Similarly, although *MSI* high tumors are associated with some unfavorable features (poor differentiation, larger size, mucinous subtype) compared to chromosomal unstable tumors, *MSI* high status confers a marked survival advantage. The elucidation of interacting transformational pathways will be paramount to our understanding of colorectal cancer and to the design of more specific treatment or prevention strategies.

DIAGNOSIS

Symptoms

Colorectal cancer is diagnosed during the evaluation of a symptomatic patient or during screening or surveillance of asymptomatic patients. The symptoms of colorectal cancer tend to be nonspecific, such as vague intermittent abdominal pain, weight loss, sensation of bloating, bleeding per rectum, and at more advanced stages nausea and vomiting. Bleeding may present as melena, which is more commonly associated with right-sided colon cancers, or as gross red blood, associated with left-sided colon and rectal cancers. Lesser amounts of bleeding may be detected on a fecal occult blood test. Patients with chronic blood loss may develop iron deficiency anemia, resulting in fatigue and even cardiac symptoms.

Malignant obstruction can result in crampy abdominal pain with nausea and vomiting. In the presence of obstruction, a perforation may develop either at the site of the tumor or through the proximal uninvolved intestine. With rectal tumors, compromise of the rectal reservoir can cause a change in bowel habits, such as constipation, decreased stool caliber, or even overflow diarrhea with changes in continence. With locally advanced rectal cancers, symptoms of tenesmus, urgency, and perineal pain can occur.

Screening

Screening and Diagnostic Tests. Screening refers to testing that is applied to an asymptomatic group without prior disease to identify those at greater risk for disease. Screening tests should demonstrate simplicity, accuracy and reliability, safety, cost-effectiveness, and good compliance. A broad range of screening and diagnostic studies can be used in the evaluation of a suspected large-bowel cancer. The least expensive and potentially most informative study for rectal tumors is a thorough digital examination geared toward localization of distal rectal and anal neoplasms. An appropriate digital exam should include sensitivity to patient privacy and discomfort, proper positioning, alerting the patient before palpating, noting landmarks (puborectalis muscle and coccyx posteriorly, bilateral ischial tuberosities, prostate anteriorly in men). The examiner should attempt to palpate the levator muscles and complete prostate and note presence of anatomic abnormalities and masses, as well as sphincter function with squeeze and push efforts. The recorded findings should not rely on a clock orientation, which changes depending on positioning. Instead, right, left, anterior, and posterior orientation should be used.

The fecal occult blood test (*FOBT*) is the most commonly used screening test for colorectal cancer. Stool samples are placed on guaiac-impregnated paper slides that change color in the presence of peroxidase activity from hemoglobin. Patients are instructed to test two samples from three consecutive bowel movements. Several factors affect the utility of this test. First, not all colonic cancers or polyps are associated with

FOBT, fecal occult blood test, unhydrated; CRC, colorectal cancer.

bleeding, and even in those that are, bleeding is often intermittent in nature. Second, patients must be instructed to remain on diets low in peroxidase (no red meat or horseradish) before testing to avoid false-positive results. Third, certain medications, such as iron, cimetidine, antacids, and ascorbic acid, may interfere with the peroxidase reaction and lead to a false-negative result. The experience with annual, nonhydrated fecal occult blood testing in asymptomatic populations has shown that about 2.5% of tested patients have positive results. Among these, only 10% to 15% have colorectal cancer.⁷² Thus, a positive screening FOBT would necessarily lead to a more specific diagnostic test, colonoscopy, which would lead in turn to the opportunity for biopsy or polypectomy. After 18 years of follow-up, the Minnesota Colon Cancer Control Study⁷³ determined that, even with 50% to 75% compliance, annual FOBT use decreased the incidence of colorectal cancer by about 20%. Table 68.4 compares test characteristics of FOBT and other traditional screening and diagnostic examinations described in the paragraphs that follow.

Rigid sigmoidoscopy with a 25-cm instrument is comparatively inexpensive but is limited by the length of intestine that can be examined and by patient compliance. Flexible fiberoptic sigmoidoscopy has gained more acceptance. Instruments measuring 35 and 65 cm are available, and an examination of the sigmoid colon and rectum can usually be performed after cleansing enemas have been administered. Patient comfort is much higher than with rigid sigmoidoscopy. In addition, the ability to perform this test adequately without a total bowel cathartic and without sedation have a positive influence on patient compliance. Because of the risk of retained methane gas, electrocautery-assisted biopsy is unsafe.

Colonoscopy with the 180-cm fiberoptic instrument is the most widely used diagnostic study to evaluate the colon, and use has increased substantially in recent years.⁷⁴ For some time, direct evidence of an association between colonoscopy and decreased colorectal cancer deaths after colonoscopy was lacking. However, recent case-matched, population-based data indicate a colonoscopy-associated 20% reduction in deaths from left-sided colon cancers.⁷⁵ Others have reported that diagnosis of advanced neoplasms decreased by more than 20% when colonoscopic screening increased threefold in the general population.⁷⁶

A valuable aspect of this procedure is the ability not only to obtain mucosal biopsy specimens but to perform polypec-

tomies. That is, colonoscopy provides both diagnostic and therapeutic benefit, making it the accepted criterion standard for assessing other screening and diagnostic tests. Data from the National Polyp Study⁷⁷ indicate a lower rate of cancer among patients who have undergone colonoscopic polypectomy. Thus, colonoscopy is the only screening test that can potentially prevent cancer development. Unfortunately, colonoscopy is also the only cancer screening test with an associated mortality rate. The incidence of severe complications that require surgical intervention (e.g., hemorrhage, perforation) is 0.1% to 0.3%.

The barium enema is an historic study for the diagnosis of colonic polyps and cancers. The double-contrast technique in which air insufflation is used is superior to the standard single-contrast barium enema to detect early polyps or cancers. The classic apple core defect has been described for colonic cancers (Fig. 68.6). Colonoscopy has largely supplanted use of barium enema, but the exam is still useful in the setting of strictures or adhesions that cannot be negotiated with a flexible scope. Another advantage of barium enema over colonoscopy is the routine visualization of the right side of the colon, which is not possible in 5% to 10% of colonoscopic examinations.

Two emerging screening tests are virtual colonoscopy or computed tomography (CT) colonography and stool DNA (sDNA) screening. CT colonography was introduced in 1994⁷⁸ and has gradually captured public appeal due to its potential to improve patient comfort, minimize risk, and eradicate the need for sedation. After air insufflation of the prepared colon, thin-cut axial images are gathered by a high-speed helical CT scanner; both prone and supine scans are obtained in minutes. Based on both image sets, the two-dimensional axial images are reconstituted into three-dimensional replications of the entire colon (Fig. 68.7). Another advantage of this technique is good visualization of the entire colon, including antegrade and retrograde views of haustral folds that sometimes elude the traditional colonoscopist.

It must be noted that CT colonography is not diagnostic; that is, patients with positive findings must undergo a traditional colonoscopy for biopsy or polypectomy. Among high-risk patients, per-patient sensitivity and specificity as high as 92% and 94%, respectively, for patients with polyps or lesions greater than 6 mm have been reported from a single center.⁷⁹ An early multicenter trial examined high-risk patients in nine different institutions and reported a combined sensitivity of

FIGURE 68.6. Surgical specimen with correlating barium enema examination of an invasive sigmoid carcinoma. **A:** The tumor is a circumferential lesion. **B:** The barium enema study demonstrates features of the apple core defect (arrows).

only 39% for lesions greater than 6 mm with high interobserver variation.⁸⁰ This study has been criticized for its reliance on older technology and high interobserver variation. Such issues may more accurately reflect broadscale generalizability or alternatively may simply indicate a need for methodical credentialing prior to institutional adoption of this technique.

As a rule, test accuracy improves as lesions increase in size, but screening test accuracy declines with decreasing prevalence of disease. It follows that CT colonography test characteristics are less positive among the average-risk population. Table 68.5 demonstrates the range of CT colonography test characteristics based on more recent studies.^{81–84} Sensitivity and specificity vary by lesion size and technique, but per patient specificity and negative predictive value is consistently robust even for lesions less than 10 mm. A strong negative-predictive value indicates that a negative test result reliably reflects a lesion-free state; that is, patients with a negative test result may safely forego invasive conventional colonoscopy. False-negative and false-positive results in CT colonography are due primarily to retained stool, which can be minimized by a full bowel cathartic. Stool tagging techniques can also help to distinguish small lesions from fecaliths that adhere to the mucosa despite repositioning.⁸⁵

Stool DNA screening refers to PCR-analysis of sloughed mucosal cells in stool, seeking genetic alterations associated with colorectal cancer. Despite technically challenging contaminants, stool is a useful medium for development of such tests because it reflects mucosal cells from the entire colon. Although the sequence of genetic changes in colorectal cancer is well documented, screening for any of these markers individually may be a painstaking process with no better accuracy than the well-entrenched fecal occult blood test. Conversely, a screening method for some optimal combination of genetic markers can be very useful. Among specimens from known cancer patients, early feasibility studies demonstrated 71% to 91% sensitivity and greater than 93% specificity searching for a combination of K-ras, p53, APC, BAT-26, and long-segment DNA indicating extinguished apoptosis.^{86,87} A recent multicenter cohort study of more than 4,400 average-risk patients compared fecal DNA screening to FOBT, using follow-up colonoscopy as a standard.⁸⁸ Sensitivity for invasive cancer

was 51.6% versus 12.9%, respectively; specificity was 94.4% versus 95.2%, respectively. A newer version of sDNA with purported better test characteristics has become commercially available recently. Concerns about cost-effectiveness relative to FOBT^{89,90} may require updating pending greater experience with use and better data-appropriate frequency.

Screening Regimen and Surveillance Recommendations. The previous section described goals and characteristics of screening tests. Screening regimens, that is the periodic application of these tests, should be undertaken for diseases that are serious, prevalent, and curable with early diagnosis. Colorectal cancer is clearly a serious health issue, resulting in approximately 50,000 deaths per year. The increased prevalence among those older than 60 years of age justifies recommendations to begin screening at age 50 years for average-risk individuals. Last, effective treatment is available and earlier stage at diagnosis is associated with better outcome, implying that screening that results in early diagnosis and initiation of treatment confers a survival benefit.

Screening for colorectal cancer begins with risk stratification to determine the appropriate timing of initiation and follow-up. Table 68.6 delineates different risk categories, including average risk, moderate risk, and high risk. For average-risk individuals, no one strategy currently dominates the others in combined cost-effectiveness, patient safety, and compliance.⁹¹ Therefore, the U.S. Multisociety Task Force on Colorectal Cancer (USMSTF) has endorsed various cost-effective screening regimens for asymptomatic, average-risk individuals beginning at age 50 years.⁹² Updated recommendations from the USMSTF for average-risk patients have separated tests into polyp and cancer screening tests (structural tests) and cancer screening tests (stool tests), with a strong emphasis on cancer prevention through use of the former (Table 68.7).

Flexible sigmoidoscopy with insertion to 40 cm or the splenic flexure is the simplest structural examination and can be performed in a clinic setting after only a partial bowel preparation with enemas. Approximately 70% of all large-bowel polyps and cancers should be within reach of a flexible sigmoidoscope. Positive flexible sigmoidoscopy must be followed by full colonoscopy. A study of 3,121 veterans demonstrated that

FIGURE 68.7. Prominent ileocecal valve with an associated tumor. **A:** Identified on two-dimensional axial computed tomography image, sagittal view. **B:** Identified on two-dimensional axial computed tomography image, coronal view. **C:** Identified on reconstituted three-dimensional virtual colonoscopy image. **D:** As pictured on colonoscopy performed for biopsy.

flexible sigmoidoscopy, followed by full colonoscopy if a distal polyp was found, would identify 70% to 80% of patients with proximal neoplasia.⁹³ A recent randomized trial comparing flexible sigmoidoscopy to FOBT found that the tests were equally likely to identify cancers (4 per 1,000 and 3.5 per 1,000 screening exams, respectively), but that flexible sigmoidoscopy was threefold more likely to identify advanced polyps (size ± 10 mm, villous features, or high-grade dysplasia).⁹⁴ Current recommendations for average-risk individuals include flexible sigmoidoscopy once every 5 years, alone or paired with annual FOBT.

Studies of colonoscopic screening efficacy have been limited by an inability to distinguish screening from diagnostic indications.^{75,76} In the classic National Polyp Study, patients who underwent colonoscopy and subsequent removal of benign polyps were followed with periodic colonoscopy for an average duration of 6 years.⁷⁷ A 90% decrease in colorectal cancer in patients participating in the National Polyp Study was noted in comparison with a general population registry. The USMSTF recommends colonoscopic screening every 10 years, the estimated time for transformation from an adenoma to

invasive malignancy. Recent changes in Medicare coverage to include screening colonoscopy have encouraged the use of this modality.⁹⁵

Double-contrast barium enema (DCBE) is used less commonly but remains an option among screening regimens. The DCBE provides a structural examination of the entire colon and is associated with less than 0.0001% complication rate. The accuracy of this exam is markedly poorer than conventional colonoscopy, and therefore recommended examination intervals have been shortened to every 5 years.

Data regarding the efficacy of CT colonography was recently deemed sufficient to include it as a recommended screening regimen at 5-year intervals.⁹² Because of persistent questions regarding test characteristics in specific subpopulations, such as the elderly, the Center for Medicare and Medicaid Services has declined to cover CT colonography as a screening regimen. As data with respect to safety, cost, and standardization of techniques disseminate, this issue is likely to be revisited.⁹⁶

The annual or biennial fecal occult blood test remains the only purely screening regimen that has been shown to directly

reduce colorectal cancer mortality. The results of four separate trials comprising more than 400,000 persons with follow-up from 8 to 18 years are summarized in Table 68.8.^{73,97-100} Based on intention to treat (screen), annual FOBT was associated with a 33% decrease in colorectal cancer mortality. With exclusion of the noncompliant patients from the Minnesota study, the observable reduction in colorectal cancer mortality would approximate 50%. Clearly, improving compliance with screening can have a major impact on colorectal cancer mortality. Eliminating dietary restrictions may improve patient compliance, as with the newer guaiac-based fecal immunochemical tests.¹⁰¹ Updated recommendations for the fecal occult blood testing regimen among average-risk adults from the USMSTF includes (i) annual, unrehydrated FOBT with dietary restriction or fecal immunochemical test without restriction, (ii) testing of two samples from three consecutive bowel movements, and (iii) following a positive screening test result with diagnostic colonoscopy.

Currently, about 60% of Americans older than age 50 years have undergone any colorectal cancer screening.¹⁰² It is hoped that choosing a screening regimen based on patient and provider preferences and resources will enhance screening compliance. Although colorectal cancer mortality is decreased with screening, it is unclear whether the overall mortality of the screened populations is different from that of the control groups. Mortality may be shifted to other causes (e.g., cardiovascular deaths) in the screened population. Cost-effective analyses⁹¹ indicate that all of the recommended colorectal cancer screening strategies cost between \$10,000 and \$25,000 per year of life saved, that is, substantially less than the cost for other currently recommended screening measures (i.e., mammography).

Patients with known disease or a personal history of polyps or cancer are in a separate surveillance category. Surveillance is defined as routine collection of data from a population known

to be at high risk for disease. For the purposes of colorectal cancer, this includes patients with inflammatory bowel disease or a personal history of polyps or cancer. The USMSTF Surveillance Guidelines^{92,103,104} recommend periodic endoscopy as outlined in Table 68.9.

STAGING

Pathology

Of all large-bowel cancers, 90% to 95% are adenocarcinomas, with the remaining histologic types being squamous cell carcinomas, adenosquamous carcinomas, lymphomas, sarcomas, and carcinoid tumors. Most colonic adenocarcinomas are moderately differentiated or well-differentiated tumors. About 20% of adenocarcinomas are poorly differentiated or undifferentiated, and these are associated with a poorer prognosis. Another commonly described characteristic of adenocarcinomas is the relative amount of mucin that is produced. Ten percent to 20% of tumors are described as mucinous or colloid carcinomas based on the abundant production of mucin. These tumors are associated with a poorer 5-year survival rate in comparison with nonmucinous tumors. Other histologic features associated with a poorer prognosis include blood vessel invasion, lymphatic vessel invasion, and the absence of a lymphocytic response to the tumor.

Staging Classification

Since Dukes' original description, various staging systems based on tumor penetration through the bowel wall have been described. The standard system for staging at this time is the American Joint Committee on Cancer and the International Union Against Cancer (AJCC/UICC) staging system based on the extent of the primary tumor (T), regional node involvement (N), and metastasis (M). The TNM system is correlated with the historical Dukes and modified Astler-Coller stages in Table 68.10. The TNM method is subjected to continuous, data-driven quality improvement reviews. In contrast to the modified Astler-Coller system, the TNM system includes carcinoma in situ (Tis) and stratifies according to number of positive nodes (Fig. 68.8).

Stage 0 represents Tis tumors that do not metastasize, stage I includes T1 and T2 tumors, stage II includes T3 and T4 tumors, and stage III includes any tumors with nodal involvement (N1–N3). Stage IV includes any cancer with distant metastases.

In 2002, the TNM staging system for colorectal cancer was updated to better reflect the impact of depth of penetration and number of involved lymph nodes.¹⁰⁵ National Cancer Database evidence of significantly different survival times among more than 50,000 patients with node-positive cancer led to expansion into subcategories A, B, and C, as displayed in Table 68.10. The prognostic validity of this subclassification has been demonstrated using the SEER national cancer registry. The AJCC 6th edition revised TNM system revealed 5-year colon cancer survival rates of 93.2% for stage I, 84.7% for stage IIA, 72.2% for stage IIB, 83.4% for stage IIIA, 64.1% for stage IIIB, 44.3% for stage IIIC, and 8.1% for stage IV.¹⁰⁶

Survival of stage IIIA is notably better than that of stage IIB. Two immediate hypotheses may explain this prognostic discrepancy. First, the poorer survival rate among stage IIB patients may reflect the lack of clear recommendations for adjuvant treatment of these patients.¹⁰⁷ Second, an accurate staging system is predicated on adequate node examination. A minimum number of 12 lymph nodes examined has been associated with improved survival¹⁰⁸ and by inference with adequacy of examination. Although there is some controversy regarding the mechanism whereby survival is improved, the 12 lymph node rule—that is, examination of at least 12 lymph nodes in a colon cancer surgical specimen—has been adopted as a surveillance measure of quality of care.^{109,110}

NATURAL HISTORY

- The natural progression of colorectal cancer comprises three processes: local invasion, lymphatic spread, and hematogenous spread. Early studies by Dukes led to the theory of an orderly progression from local tumor invasion to subsequent lymphatic and hematogenous spread after the tumor had penetrated the intestinal wall. Later data have shown that tumors that do not invade through the intestinal wall can progress to lymphatic metastases or distant disease nonetheless. Thus, even patients who undergo curative resection of apparently localized colorectal cancers may harbor blood-borne metastases.

TABLE 68.10**STAGING OF COLORECTAL CANCER^a**

■ STAGE	■ DESCRIPTION
TUMOR-NODE-METASTASIS (TNM) SYSTEM	
Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of tumor in resected specimen (prior polypectomy or fulguration)
Tis	Carcinoma in situ
T1	Invades into submucosa
T2	Invades into muscularis propria
T3/T4	Depends on whether serosa is present
Serosa Present	
T3	Invades through muscularis propria into subserosa; invades serosa (but not through); invades pericolic fat within the leaves of the mesentery
T4	Invades through serosa into free peritoneal cavity or through serosa into a contiguous organ
NP Serosa (distal two thirds of rectum, posterior left or right colon)	
T3	Invades through muscularis propria
T4	Invades other organs (vagina, prostate, ureter, kidney)
Regional Lymph Node Involvement	
NX	Nodes cannot be assessed (e.g., local excision only)
N0	No regional node metastases
N1	1–3 positive nodes
N2	4 or more positive nodes
N3	Central nodes positive
Distant Metastasis	
MX	Presence of distant metastases cannot be assessed
M0	No distant metastases
M1	Distant metastases present
Stage	Description
0	Tis N0 M0
I	T1,2 N0 M0
IIA	T3 N0 M0
IIB	T4 N0 M0
IIIA	T1,2 N1 M0
IIIB	T3,4 N1 M0

MAC C1	T2, N1, M0; T2, N2, M0 (stage III)
MAC C2	T3, N1, M0; T3, N2, M0 (stage III) T4, N1, M0; T4, N2, M0 (stage III)
MAC C3	T4, N1, M0; T4, N2, M0 (stage III)

^aIn all pathologic staging systems, particularly those applied to rectal cancer, the abbreviations m and g may be used; m denotes microscopic transmural penetration; g or m + g denotes transmural penetration visible on gross inspection and confirmed microscopically.

FIGURE 68.8. Schematic description of the staging systems with respect to depth of invasion.

Therapies designed to reduce the development of recurrent disease after surgical resection are discussed in later sections of this chapter.

Often local growth of an adenocarcinoma is characterized by intramural expansion of the tumor into the bowel lumen. Subsequent lateral invasion into the intestinal wall usually progresses in a transverse direction rather than longitudinally and thereby leads to circumferential involvement of the intestine. Although the incidence of lymphatic metastasis increases with extent of local invasion through the intestinal wall, 10% to 20% of patients with cancer limited to the submucosa are found to have positive lymph nodes.

The liver is the most common site of hematogenous spread of colorectal cancer; liver metastasis occurs in about half of all cases eventually.¹¹¹ The liver is the first capillary network exposed to tumor emboli traveling through the portal system and represents the major site of venous drainage of the colon and upper rectum. The liver can be the sole site of tumor metastasis, as evidenced by the successful resection of liver metastases for cure in selected patients. By contrast, the lower rectum has a dual drainage system, draining into the portal system and the vena cava by way of the middle and inferior hemorrhoidal veins, respectively. Isolated lung metastases can develop from lower rectal tumors when tumor emboli travel through the systemic venous drainage system. The lung is the second most common site of metastasis from colorectal tumors. Tumor involvement of other sites in the absence of liver and lung metastases is unusual. In certain circumstances, isolated bone metastases to the sacrum or vertebral bodies can arise when tumor emboli travel through portal-vertebral venous communications known as the Batson plexus.

Another potential mode of spread is by intraluminal or extraluminal exfoliation of tumor cells with subsequent implantation. Tumor implantation may occur during surgical resection; spillage of tumor cells can cause recurrences in bowel anastomoses,

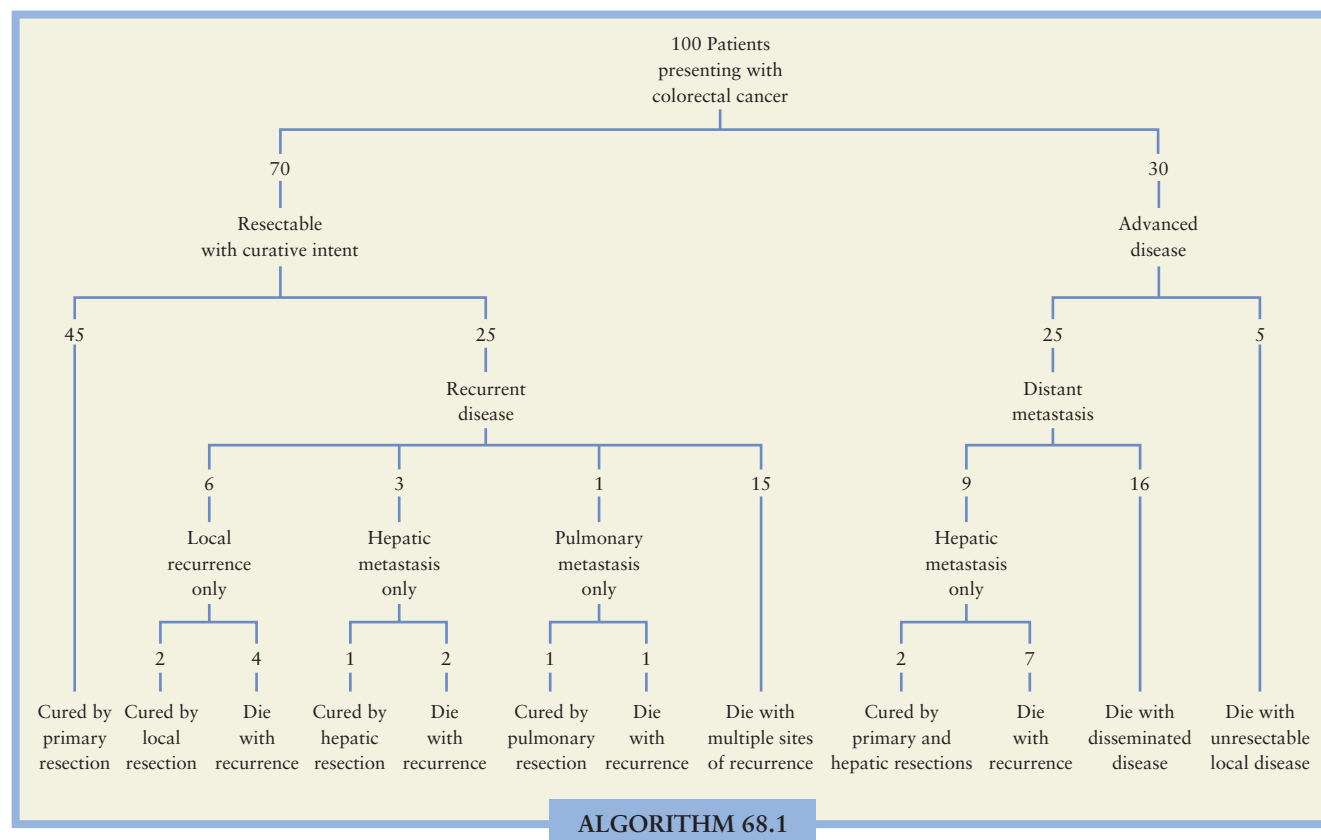

abdominal incisions, or other intra-abdominal sites. When tumors penetrate the intestinal wall, shed tumor cells can be implanted intraperitoneally and cause peritoneal carcinomatosis.

A summary of the natural history of patients who present with colorectal cancer is depicted in Algorithm 68.1.¹¹¹ For every 100 patients initially evaluated, 30 have clinically evident distant spread, and the remaining 70 undergo resection for localized disease. Among these 70 patients, 45 are cured and disease recurs in the remainder. Extrapolation of these figures to the approximately 150,000 patients in whom colorectal cancer is diagnosed each year in the United States implies that 67,500 patients can be cured with surgical resection alone; disease recurs in the remaining 82,500 patients after resection, or they have disseminated tumor at the time of diagnosis.

TREATMENT

Primary Colorectal Tumors

Neoplastic Polyps. Endoscopic polypectomy is the standard approach for the treatment of advanced polyps (size ≥ 10 mm, villous features, or presence of high-grade dysplasia) unless it is medically contraindicated. Most pedunculated polyps can be removed with a snare endoscopically. Frequently sessile lesions can be removed piecemeal, but several sessions may be required. A resected lesion with a malignant focus presents a dilemma regarding whether to subject the patient to the risks of colectomy. Lesions that are (i) low grade, (ii) without mucosal penetration, (iii) with resection margin greater than 2 mm, and (iv) without lymphovascular invasion should be considered a malignancy in situ that is exceedingly unlikely to metastasize and therefore does not require further surgery.^{112–115} If the lesion penetrates the muscularis mucosa, it is an invasive cancer and surgical resection should be strongly considered.

ALGORITHM 68.1. The natural history of colorectal cancer.

Occasionally, colectomy with resection of paracolic lymph nodes is performed without evidence of residual disease or nodal metastases and the patient goes on to develop widespread metastases. Such a scenario likely reflects aggressive tumor biology refractory to the local control provided by resection.

Large villous tumors of the rectum can pose a therapeutic challenge. Total excision is required to assess the presence of invasive cancer accurately and prevent recurrence, which is estimated to occur in up to 40% of cases. A full-thickness transanal excision with sphincteric muscle and mucosal approximation is preferred and can be facilitated by transanal microscopic endosurgery techniques. However, other approaches, such as low anterior resection, coloanal procedures, or abdominoperineal resection, may have to be used to excise extensive benign rectal lesions totally.

Invasive Colorectal Cancers

Surgery. Surgical options for colorectal cancer depend on the location of the primary tumor. These surgical procedures are summarized in Table 68.11.

Before surgical resection, evaluation for metastatic disease is important. A careful physical examination determines the presence of hepatomegaly, ascites, or adenopathy. Except in the case of an obstructing lesion, a preoperative CT scan has become *de rigueur*. For rectal tumors, the distance of the tumor from the anal verge and its mobility are important in assessing resectability and the type of operation required. Rectal ultrasonography or magnetic resonance imaging are excellent methods for preoperative assessment of local invasion, sphincter involvement, and the presence of enlarged lymph nodes within the mesorectum (Fig. 68.9). Laboratory studies should include a complete blood cell count; a comprehensive metabolic panel to assess nutritional status, serum liver enzymes, and renal function; and a carcinoem-

bryonic antigen (CEA) assay. Determination of a baseline CEA level can be useful in subsequent follow-up of the patient as well as assessment of potential metastases. The presence of metastatic disease may alter the planned surgical procedure and lead to preliminary treatment with chemotherapy or to a more extensive resection. In the unobstructed patient, a full colonoscopy or double-contrast barium enema should be performed to rule out the presence of synchronous colorectal cancers.

The surgical goals in the resection of a primary colorectal cancer are to achieve an en bloc resection that encompasses an adequate amount of normal colon proximal and distal to the

tumor, to obtain adequate lateral margins if the tumor is adherent to contiguous structures, and to remove regional lymph nodes. Accomplishment of these goals optimizes the chance of preventing locoregional recurrence of the disease. The extent of bowel resection has been the subject of numerous debates. In pathologic studies, tumor rarely extends intramurally more than 2 cm beyond the area of gross involvement. Traditionally, 5 cm of normal large intestine proximal and distal to the tumor has been advocated as a margin that is adequate to encompass intramural spread completely. The actual margin of intestine removed is often determined by the extent of the lymphadenectomy. The draining lymph nodes to be removed as part of a curative resection include nodes along the named feeding artery (Fig. 68.10). In the event that the tumor is between named arteries, intraoperative judgment should address whether both basins must be removed. Extensive resections of bowel along with more central or retroperitoneal lymph nodes are not indicated because they add minimal oncologic benefit and substantially increase operative complications. At the time of surgical resection, the abdominal viscera, particularly the liver and peritoneal surfaces, should be thoroughly investigated. If evidence of disseminated disease is apparent, a less extensive resection of the pri-

mary lesion for palliation to avoid complications of obstruction or bleeding may be indicated.

Intraperitoneal Colon and Upper Third of the Rectum. The surgical resection of cancers in different sites in the colorectum requires attention to specific anatomic details. Resection plus primary anastomosis is the surgical procedure of choice for cancers of the colon and upper and middle third of the rectum. While use of mechanical bowel preparations is in decline, oral antibiotics should be considered preoperatively to reduce infectious complications. The choice of anastomotic technique (i.e., stapling vs. hand sewing) depends on the surgeon's preference.

Tumors of the cecum and ascending colon should be resected by a right hemicolectomy. Ligation of the ileocolic, right colic, and right branches from the middle colic artery is required (Fig. 68.10). For tumors in the hepatic flexure, an extension of a right hemicolectomy is performed with ligation of the middle colic artery near its origin. Care must be taken during the mobilization of the ascending colon and hepatic flexure because the right ureter and testicular or ovarian vessels, inferior vena cava, superior mesenteric vein, and duodenum are all in proximity.

FIGURE 68.10. Segmental resections for cancers of the colon and upper third of the rectum.

For lesions of the transverse colon, a transverse colectomy is accomplished by proximal ligation of the middle colic artery (Fig. 68.10). Cancer of the splenic flexure can be treated with a segmental resection in which the middle transverse colon is anastomosed to the middle descending colon. For this procedure, the left colic artery is divided and the middle colic artery is preserved. Mobilization of

the splenic flexure requires care to avoid injury to the spleen.

A left hemicolectomy with removal of intestine from the middle transverse to the distal sigmoid colon can be used for tumors of the descending colon (Fig. 68.10). High ligation of the inferior mesenteric artery is necessary in this operation. For cancers of the sigmoid colon, a segmental resection can be

FIGURE 68.11. Extent of surgery in abdominoperineal resection.

performed with ligation of the sigmoid artery near its origin. Rectosigmoid cancers and tumors confined to the upper third of the rectum are removed by an anterior resection. The upper third of the rectum is about 12 to 16 cm from the anal verge and is located above the peritoneal reflection ending proximally where the tenia flare (Fig. 68.11). The pelvic peritoneum is incised circumferentially around the rectum, and the intestine is sharply mobilized from the presacral fascia. Laterally, the middle hemorrhoidal vessels are ligated. Anteriorly, the rectum is mobilized from the seminal vesicles and prostate or the vagina. The mesenteric vessels are divided at the origin of the sigmoid artery or higher, at the origin of the inferior mesenteric artery, if further mobilization of the splenic flexure is required to obtain a tension-free anastomosis.

Laparoscopic and hand-assisted laparoscopic techniques have been widely adopted for resection of colon and upper rectal cancers. Although the operative steps and surgical principles are identical, laparoscopic resection for colorectal cancer was met initially with skepticism. Critics questioned potential for port-site metastases, possible inadequacy of resection, compromise of patient safety, and increased cost and time investment for questionable gain. The Clinical Outcomes and Surgical Therapy (COST) Study Group¹¹⁶ and others¹¹⁷ have reported no difference in perioperative complications, cancer recurrence, or overall survival at 3-year follow-up. A large cohort study from the National Cancer Database recently compared overall survival after laparoscopic and open colon cancer resection.¹¹⁸ After case mix adjustment, overall survival was improved for patients who underwent laparoscopic resection of stage I and II but not stage III colon cancer.

Middle and Lower Third of the Rectum. Cancers located in the lower third of the rectum, between the anorectal ring and 7 to 8 cm from the anal verge, are reliably treated by abdominoperineal resection. The procedure involves wide excision of the rectum to include the lateral attachments and pelvic mesocolon and establishment of a colostomy. The extent of surgery for an

abdominoperineal resection is illustrated in Figure 68.13. With the patient in a modified lithotomy position, the abdominal and perineal procedures can be performed simultaneously by two teams or sequentially by one team. Alternatively, the abdominal procedure can be completed with the patient in the supine position, and the perineal portion completed afterward, with the patient turned in the lateral position. On opening of the abdomen, evidence of intra-abdominal spread is ascertained. The discovery of extensive disseminated disease may eliminate the need for an abdominoperineal resection because a local excision or fulguration to preserve anal function may be more appropriate for palliation. If an abdominoperineal resection is performed, ligation of the superior rectal artery at its origin, along with the superior rectal vein, is required. Occasionally, if extensive nodal disease is present, higher arterial ligation may be necessary. The rectum is mobilized in a fashion similar to that described for an anterior resection, but the dissection is carried down to the pelvic floor muscles, which are excised en bloc with the anus. An end-sigmoid colostomy is brought out through the rectus sheath. Efforts to exclude small intestine from a future radiation field by use of the omentum should be considered. Primary closure of the perineal wound over drains often can be accomplished, but a greater than 50% wound infection rate is to be expected. Use of gracilis or other muscle flaps at the time of perineal wound closure should be considered in patients who have undergone neoadjuvant radiation.

Middle and Lower Third of the Rectum. Cancer of the middle third of the rectum, between 8 and 12 cm from the anal verge (Fig. 68.14), can be managed by various techniques. For these tumors, abdominoperineal resection does not yield results superior to those of other procedures that spare the anal sphincter. Therefore, an effort should be made to maintain intestinal continuity. Low anterior resection is a commonly used technique that involves resection of the middle rectum with primary anastomosis. The introduction of the end-to-end anastomosis stapler has increased the use of this sphincter-saving

FIGURE 68.12. Anorectal anatomy with important landmarks. Approximate measurements are relative to the anal verge. D, deep; S, superficial; Sc, subcutaneous; AR, anorectal ring; ATZ, anal transition zone.

procedure (Fig. 68.13A). If a transanal reconstruction with a stapler is contemplated, the patient should be placed in the lithotomy position. The initial stages of the operation, with complete mobilization of the rectum to the level of the pelvic floor, are identical to those for an abdominoperineal resection. After removal of the tumor, an end-to-end or end-to-side anastomosis is joined with sutures or staples (Fig. 68.13B and C). After ascertaining an airtight anastomosis, a temporary transverse colostomy or loop ileostomy is recommended for patients in whom preoperative radiation was used, the anastomosis is up to 4 cm from the anal verge, or the integrity of the anastomosis is a concern.

Other sphincter-saving approaches have been described for middle rectal cancers.¹¹⁹ Coloanal anastomosis involves restoring bowel continuity by bringing the colon to the level of the anus and dentate line (Fig. 68.13D). A straight coloanal anastomosis commonly results in stool frequency, urgency, and incontinence for the first year postoperatively. These symptoms can be tempered by a side-to-end anastomosis or a formation of a colonic J-pouch (Fig. 68.13E). Creation of an adequate but not overlarge reservoir is an important technical point to avoid future difficulty with evacuation.

A controversy in sphincter-saving procedures for rectal tumors concerns the length of an adequate distal mucosal margin. The traditional dictum of 5 cm for a margin is not evidence based. Only 2.5% of patients have intramural spread beyond 2 cm from the palpable tumor—and these patients usually have dissemination of tumor despite aggressive local therapy. No correlation has been found between local recurrence and extent of the distal margin when it is greater than 2 cm. Ideally, a surgical margin of 3 cm, measured on the fresh specimen, should be achieved. If the end-to-end anastomosis stapler is used, then a margin of 2 cm plus the additional “doughnut” specimen obtained by the stapler should be adequate. The segment of rectum located between the tumor and the pelvic floor, determined preoperatively, can be lengthened as much as 4 cm after the rectum is mobilized from its pelvic attachments (Fig. 68.14). If in the surgeon’s judgment an adequate margin cannot be obtained, then abdominoperineal resection should be performed.

Radial margins are more relevant than longitudinal margins for local control of mid to low rectal cancers. The practical importance of lateral spread is demonstrated by results of total mesorectal excision (TME) en bloc with the rectal specimen. By means of TME, the Basingstoke group initially reported a dramatic reduction in local recurrence from the norm of 30% to 40% to 3.7% over a 4-year follow-up period.¹²⁰ Subsequent studies consistently showed a decline in local recurrence of 15% to 40% using conventional techniques to 4% to 11%

using TME.^{121–124} The technique of TME includes sharp dissection posteriorly in the presacral avascular plane from the superior hemorrhoidal vessels to the levator ani, laterally encompassing the entire peritoneal reflection, and anteriorly including Denonvilliers fascia in the specimen (Fig. 68.15).

As with many oncologic surgical procedures, increased interest has been shown in less radical types of surgery to manage cancers of the middle and lower third of the rectum in an effort to preserve the anal sphincters and avoid an abdominoperineal resection. Initially, these local procedures, such as excision, ablation, and irradiation, were reserved for patients with advanced disease or with medical contraindications to radical surgery. However, for selected patients with low rectal cancers, local excision is an acceptable treatment option that is associated with rates of local recurrence and survival similar to those seen after radical surgery. A multicenter, prospective study was undertaken to address this question.¹²⁵ To be eligible, patients had to have an adenocarcinoma of the rectum that was 10 cm or less from the dentate line and 4 cm or less in diameter, and that involved 40% or less of the rectal lumen. All patients registered underwent local excision of their tumor. Those determined to have T1 tumors with negative surgical margins received no further treatment, and those with T2 tumors underwent postoperative radiation and chemotherapy. The 6-year disease-free survival rates were 83% and 87%, respectively, and the overall survival rates were 71% and 85%, respectively, for T1 and T2 tumors. Two of 59 patients with T1 tumors and 7 of 51 patients with T2 tumors experienced an isolated local recurrence and underwent salvage abdominoperineal resection. Four of these died of recurrent local or distal disease.¹²⁵ A case-control study from the Minnesota group examining transanal excision versus radical surgery without adjuvant therapy found a significantly higher local recurrence rate of 47% versus 6%, respectively.¹²⁶ More important, T2 patients undergoing local versus radical initial excision experienced a respective 5-year survival difference of 65% versus 81% among patients with T2 tumors, in spite of salvage abdominoperineal resection. Detailed prospective data to better understand 3-year survival and other outcomes of preoperative chemoradiotherapy followed by transanal excision of uT2N0 rectal tumors are currently being collected through the American College of Surgeons Oncology Group protocol Z6041.¹²⁷

Other forms of local treatment for low rectal cancers are reserved for patients who are not candidates for abdominoperineal resection or local excision. Ablation by transanal electric fulguration of the tumor in multiple stages has been reported to be an acceptable treatment in patients who are poor surgical candidates; however, this procedure cannot be used for

circumferential tumors.¹²⁸ Endocavitary irradiation as a primary curative therapy for early cancers has been reported with some success. The neodymium:yttrium-aluminum garnet laser has been found to be effective in palliating obstructive or bleeding lesions of locally advanced colorectal tumors.

Adjuvant Radiation Therapy

Radiation therapy combined with surgical resection for colorectal cancer has been demonstrated to reduce the incidence of local tumor recurrence. In general, the use of radiation therapy

FIGURE 68.14. Dissection of the rectum from pelvic attachments lengthens distal tumor-free margins and may permit a sphincter-saving procedure.

has been limited to rectal tumors in which the incidence of local recurrence is significant, including those extending through the intestinal wall or with lymph node involvement. Overall, for stage IIA (T3N0) rectal tumors, the incidence of local recurrence is about 30% to 35% but can be reduced to 5% with adjuvant radiation therapy. For stage III (any T, N1–2) rectal cancers, the use of adjuvant radiation therapy decreases local recurrences from the range of 45% to 65% down to 10%. Multiple phase III studies of adjuvant and neoadjuvant radiation have demonstrated improved local control.¹²⁹ Although no survival advantage has been shown at 2 years follow-up, one randomized controlled trial revealed an overall 5-year survival rate of 58% for radiation plus surgery versus 48% for the surgery alone group.¹³⁰

The technical aspects of radiation therapy relate to dose and timing. The effectiveness of radiation therapy is directly proportional to the total dose. It appears that the most effective dose of radiation to eradicate microscopic disease is at least 5,000 cGy. Adjuvant radiation therapy can be delivered preoperatively, postoperatively, or in a combined “sandwich” approach, in which small doses of preoperative treatment are followed by postoperative treatment to a high total cumulative dose. Recent data from a randomized trial of preoperative versus postoperative therapy for Stage II and III patients indicate no overall survival superiority. However, patients who received preoperative therapy experienced only a 6% rate of local recurrence and significantly fewer toxic effects than the postoperative radiotherapy group who had a 12% rate of local recurrence.¹³¹

Adjuvant radiation therapy for colon cancer is associated with special problems of toxicity because of the large amount of small intestine that may lie within the treatment field. Nevertheless, several reports indicate that in high-risk cases, such as

ALGORITHM 68.2. An algorithm for intensive combined, targeted chemotherapy for metastatic colorectal cancer. (Adapted from Goldberg RM, Carrato A. Accomplishments in 2007 in the treatment of advanced colorectal cancer. *Gastrointest Cancer Res* 2008;2(3 suppl):S19–S24.)

tumors involving adjacent viscera or perforated lesions, adjuvant radiation therapy can decrease local and regional recurrences.

Adjuvant Chemotherapy

Even if local tumor control is adequate, patients with colorectal cancer die of disseminated disease. In about 25% of patients with stage II tumors, and 50% of those with stage III tumors, the growth of micrometastatic disease present at the time of primary tumor resection eventually causes death. Several randomized, prospective studies have demonstrated adjuvant systemic chemotherapy benefit to certain subgroups of patients.

The National Comprehensive Cancer Network (NCCN; <http://www.nccn.org/index.asp>) is a consortium of major cancer centers in the United States that have established practice guidelines for various cancers based on the best evidence available. For node-negative colon cancers, adjuvant chemotherapy may be considered for high-risk lesions (i.e., T4, grade 3–4, lymphovascular invasion, bowel perforation, or bowel obstruction).¹³² For the 60% of colorectal cancers diagnosed at stage III or IV, adjuvant chemotherapy is recommended. The standard chemotherapy regimen has traditionally been 5-fluorouracil (5-FU) or its oral equivalent, capecitabine, and leucovorin, for an overall survival benefit of 15% to 20%.

More recently, the addition of oxaliplatin and irinotecan chemotherapeutic agents have substantially improved median survival times of metastatic colorectal cancer. In addition, the survival benefits of regimens that include these agents are further improved by use of new targeted biologic agents including bevacizumab, an anti-vascular endothelial growth factor monoclonal antibody, and cetuximab and panitumumab, anti-epidermal growth factor receptor monoclonal antibodies. Cetuximab should be used as the biologic agent only after ascertaining unmutated, wild-type *K-RAS*.¹³³ The novel use of these combined agents aggressively and in continuum has led to a paradigm shift in the understanding of metastatic colorectal cancer.^{133,134}

Newer recommendations include first-line treatment of unresectable metastatic disease (absent other contraindications to surgery) aggressively with two cytotoxic agents and one biologic agent (Algorithm 68.2). The goal is to shrink the tumor until it may be surgically resected. Even if resection is not achieved, with individually targeted therapies that maximize dosing and minimize toxicities, metastatic colorectal cancer may begin to share more characteristics with chronic disease than an acute terminal illness.

In colon cancer, local recurrence is infrequent; in rectal cancer, the use of adjuvant chemotherapy combined with radiation has proved effective in improving local control and increasing the survival rate. In rectal cancer, it is almost as important to prevent local failure and ensuing symptoms as it is to prevent death from distant metastasis. As noted in the previous section, radiation therapy is routinely recommended for patients with stage IIA (T3, N0) or III (any T, N1–2) rectal cancers. In addition, the NCCN guidelines recommend adjuvant chemotherapy (either 5-FU or oxaliplatin plus fluorouracil and leucovorin [FOLFOX]) for these stages of rectal cancer.

Treatment of Recurrent Colorectal Cancer

A subset of patients with recurrent colorectal cancer can be cured, so that a comprehensive follow-up program in patients who have undergone resection of their primary tumor is appropriate (Table 68.12). Fifty percent of cancers that recur do so within 18 months after surgery, and more than 80% of recurrences are evident by 3 years. Therefore, careful follow-up is important during the 3-year period after primary tumor resection. Besides identifying recurrences, a careful follow-up program also identifies the 5% of patients in whom a metachronous primary tumor of the large intestine develops.

The CEA assay is a sensitive serologic test in the diagnosis of recurrent colorectal cancer. CEA is a glycoprotein that was originally described as a tumor-specific antigen derived from neoplasms of the gastrointestinal tract. It is now known that CEA is not tumor specific because its concentration can be elevated in various malignancies from different sites and in some benign conditions. CEA is an oncofetal antigen that is also

TABLE 68.12

GUIDELINES FOR SURVEILLANCE STUDIES AFTER RESECTION OF STAGE II OR III COLORECTAL CANCER^a

■ TEST	■ RECOMMENDATIONS
Carcinoembryonic	If patient is medically fit to undergo liver resection for liver metastases, evaluate antigen every 2–3 mo for 2 y or more; an elevated result warrants further evaluation for metastatic disease but does not justify systemic therapy for presumed disease
History and physical examination	Every 3–6 mo for first 2–3 y, biannually for next 2 years, and annually thereafter
Colonoscopy	After initial clearing colonoscopy to rule out synchronous lesions, surveillance colonoscopy at first year postoperatively. If normal, thereafter, every 3–5 y to detect new cancers and polyps
Computed tomography	Individualized
Chest roentgenography	Individualized

^aEndorsed by the American Society of Clinical Oncology.

expressed by early embryonic or fetal cells. CEA is not useful as a screening or diagnostic test but is useful as a tumor marker. The CEA concentration is elevated in more than 90% of patients with disseminated colorectal cancer and in about 20% of patients with localized disease. Serum levels usually are elevated in proportion to the mass of the tumor present and often correlate with response to therapy. CEA measurement provides useful information when elevated levels fall to normal after curative resection. In about two thirds of patients with recurrent disease, an increased CEA level is the first indicator of tumor recurrence; therefore, serial CEA testing, combined with regular physical examinations, is one of the most useful means for detecting recurrent colorectal cancer. In fact, the CEA determination, along with the history and physical examination, is the only surveillance test recommended for patients after curative resection of stage II or III disease. The NCCN guidelines recommend CEA testing along with history and physical examinations every 3 months for 2 years, then every 6 months for a total of 5 years. Colonoscopy is recommended 1 year after resection and then every 2–3 years thereafter if negative.

Hepatic Metastases

- 6 The liver is the most frequent site of blood-borne metastases from primary colorectal cancers. In a subgroup of patients, the liver is the only site of recurrent disease, and surgical excision of the metastases is the only curative option for these patients. Overall, surgical resection is associated with a 5-year survival rate of 25% to 30%.¹³⁵ Patients eligible for hepatic resection of metastatic disease are those who have no evidence of extrahepatic tumor, no medical contraindications to surgery, and a limited number of lesions that are amenable to resection with negative surgical margins.

Patients who have unresectable hepatic metastases that appear to be confined to that organ have been treated with regional chemotherapy through the hepatic artery (e.g., fluo-

rodoxyuridine). Several studies have demonstrated significantly higher tumor response rates with regional chemotherapy than with systemic chemotherapy. A meta-analysis has demonstrated that regional chemotherapy of unresectable liver metastases can confer improved survival of several months.

Pulmonary Metastases

Pulmonary metastases develop in about 10% of all patients with colorectal cancer, usually in association with widespread metastatic disease. Because the colon is drained solely by the portal system, one would not expect metastases to the lung without evidence of tumor in the liver. In contrast, rectal cancers may spread through the portal or systemic venous systems and can theoretically give rise to isolated pulmonary metastases. In selected patients, particularly those with rectal cancers, resection of pulmonary recurrences can result in a 5-year survival rate of 20%.¹³⁶

Local/Regional Recurrence

Colon cancer recurs locally in about 20% of cases, and the local lesion is the only site of recurrence in about one third of these cases. If the recurrent tumor is isolated to the suture line, resection of such recurrence can be curative. Locoregional failure occurs in 30% to 65% of patients with transmural or node-positive rectal cancers. Often, pelvic recurrences of rectal cancer after a low anterior or abdominoperineal resection are diffuse and associated with disseminated disease. If pelvic recurrences are localized, they should be resected if negative surgical margins can be achieved. Surgical procedures necessary to accomplish this include en bloc partial sacrectomy or total pelvic exenteration.

Disseminated Disease

Recurrent colorectal cancer is not usually localized to one site that is amenable to surgical resection. More commonly, colorectal cancer recurs in multiple sites. In these cases, systemic therapy may be considered. No studies have clearly documented that systemic therapies for disseminated colorectal cancer improve the survival rate; however, systemic treatment is commonly used for palliation.

The current management of disseminated colorectal cancer uses various active agents, both in combination and as single agents: 5-FU/leucovorin, irinotecan, oxaliplatin, and capecitabine and bevacizumab. The choice of therapy is based upon the performance status of the patient (i.e., whether the patient can tolerate or not tolerate intensive therapy), prior therapies, and patient preference. Patients with poor performance characteristics should receive supportive care only.

Other Colorectal Tumors

Carcinoid Tumors. Carcinoid tumors are neoplasms derived from cells that are capable of synthesizing a wide variety of hormones. Two recent reviews of the Surveillance Epidemiology and End Results database have updated our knowledge of carcinoid tumors.^{137,138} In the first study analyzing over 11,000 incident cases between 1973 and 1997, most gastrointestinal tract carcinoids occurred in the ileum, not the appendix as previously thought. The incidence of carcinoid tumors appears to have increased by about 6%.¹³⁷ However, it was not possible to discern whether the incidence increase actually represented improvements in diagnosis. In the second study of

TABLE 68.13**STAGING OF CARCINOID TUMORS**

■ STAGE	■ DESCRIPTION	
TUMOR-NODE-METASTASIS (TNM) SYSTEM		
Primary Tumor		
TX	Primary tumor cannot be assessed	
T0	No evidence of tumor in resected specimen (prior polypectomy or fulguration)	
T1	≤1 cm and any depth of invasion >1 and ≤4 cm and invades up to or including the muscularis propria	
T2	>1 and ≤4 cm and invades beyond the muscularis propria >4 cm and invades up to or including the muscularis propria	
T3	>4 cm and invades beyond the muscularis propria	
Regional Lymph Node Involvement		
NX	Nodes cannot be assessed (e.g., local excision only)	
N0	No regional node metastases	
N1	Positive regional node metastases	
Distant Metastasis		
MX	Presence of distant metastases cannot be assessed	
M0	No distant metastases	
M1	Distant metastases present	
Stage	Description	5-Year Survival Rates ^b
I	T1 N0 M0	97%
II	T1,2 N1 M0	69%
	T2 Any N	
III	T3 Any N M0	21%
IV	Any T Any N M1	17%

^aIn all pathologic staging systems, particularly those applied to rectal cancer, the abbreviations m and g may be used; m denotes microscopic transmural penetration; g or m + g denotes transmural penetration visible on gross inspection and confirmed microscopically.

^bKern KA, Pass HI, Roth JA. Surgical treatment of pulmonary metastases. In: Rosenberg SA, ed. *Surgical Treatment of Metastatic Cancer*. Vol 69. Philadelphia: JB Lippincott; 1987.

incident cases from 1973 to 2004, prognostic variables were assessed and a staging scheme was devised as a tool for more accurate prognostication (Table 68.13).¹³⁸ The authors found that tumor size continued to be an important prognostic factor. About 60% of rectal carcinoids present as asymptomatic submucosal nodules measuring less than 2 cm in diameter. Transanal local excision suffices for definitive therapy because small tumors rarely metastasize. More radical excisions of larger rectal lesions may be required for local control; however, the results of radical excisions for large rectal carcinoids are poor because these tumors are more prone to metastasize. In contrast to rectal carcinoids, colon carcinoids should be treated by standard curative operation. Among carcinoid tumors of the colon less than 2 cm in size, 22% have metastasized to regional lymph nodes, while 79% of those greater than 2 cm have positive nodes.¹³⁹

Lymphomas. Colorectal lymphomas are rare and account for fewer than 0.5% of all colorectal malignancies. The documentation of widespread dissemination of lymphoma in most cases underscores the concept that lymphoma of the gastrointestinal tract is a systemic disease in which tumor cells are present in other organ sites. Because this disease is highly responsive to chemotherapy and radiation, surgery is not the primary mode of therapy. If the clinical workup reveals a focal site of disease in the large intestine, surgical resection may be consid-

ered. Usually, for localized, low-grade colorectal lymphomas, radiation therapy is considered first-line therapy. For intermediate- and high-grade lymphomas, chemotherapy combined with radiation therapy should be the primary treatment modality. Surgery for colorectal lymphomas has been primarily for diagnostic and staging purposes and for the management of treatment-related complications (i.e., perforation or bleeding).

Sarcomas. Colorectal sarcomas are extremely rare and account for less than 0.1% of all large-bowel malignancies. The most common histologic sarcoma subtype is leiomyosarcoma. With these tumors, the most significant prognostic indicator is the tumor grade. Patients with high-grade tumors do poorly. These tumors usually metastasize to the liver and peritoneal surfaces. If the tumors are clinically localized at initial presentation, a radical en bloc excision should be performed to obtain a margin of uninvolved normal tissue. Because of the rarity of this tumor, no studies have addressed whether adjuvant radiation therapy or chemotherapy is beneficial.

Gastrointestinal Stromal Tumors. Gastrointestinal stromal tumors (GISTs) were previously often mislabelled as sarcoma. GISTs originate from the pluripotential interstitial cells of Cajal, the gastrointestinal pacemaker cell, and can occur anywhere in the gut. These are submucosal, slow-growing tumors that can reach immense sizes before becoming symptomatic.

Frozen section histology is often consistent with a spindle cell appearance; immunohistochemical staining nearly always reveals positive kit receptor. The metastatic potential is assessed by size and field mitotic index. These mesenchymal tumors spread hematogenously, generally recurring locally in the peritoneum or in the liver. The mainstay of treatment is complete surgical resection. GISTs are not responsive to traditional chemotherapy or to radiation. For metastatic disease, a tyrosine kinase inhibitor, imatinib mesylate, is effective at controlling tumor growth and spread.

CHAPTER 69 ■ DIVERTICULAR DISEASE

LAUREN KOSINSKI, KIRK LUDWIG, AND MARY OTTERSON

KEY POINTS

- 1 Diverticulosis and its complications are common in Western societies.
- 2 Sigmoid and left colon involvement predominate in non-Asian industrialized nations; the rectum is spared.
- 3 Lack of dietary fiber, colonic anatomy, and disordered colonic motility are likely contributors to the development of diverticulosis.
- 4 Computed tomography imaging markedly improves diagnostic accuracy and treatment planning.
- 5 Early, judicious use of contrast enema studies or colonoscopy can safely help distinguish diverticular stricture from cancer.
- 6 Antibiotic therapy, bowel rest, and percutaneous drainage of diverticular abscesses can often convert surgical emergencies into elective operations.
- 7 Bowel resection with primary anastomosis and temporary, diverting loop stoma is favored in acute cases when possible; single-stage operations are preferred for elective cases.

Diverticular disease is one of the most common problems treated by surgeons, and management strategies have evolved significantly in the last 10 years. A short time ago, virtually all cases of acute diverticulitis were treated as surgical emergencies. Patients routinely underwent staged procedures and were taken to the operating room for sigmoid colectomy and temporary end-colostomy within hours of admission. Surgical and radiologic innovations have introduced less invasive options for managing even complex disease. Surgery, when necessary, is often performed electively or semielectively.

Key among recent major shifts in the diagnosis and management of diverticular disease are (a) strategies for converting diverticular surgical emergencies into single-stage, elective operations with avoidance of a colostomy; (b) utilization of computed tomography (CT) imaging for diagnosis and CT-guided percutaneous drainage of diverticular abscesses; (c) reconsideration of indications for elective surgery; and (d) emergence of laparoscopic surgical techniques as state-of-the-art approaches for diverticular disease.

CLASSIFICATION

- 1 Diverticulosis refers to the presence, whether symptomatic or asymptomatic, of colonic diverticula. In common medical usage, this refers to the presence of pseudodiverticula, a very common acquired condition in Western societies, in which mucosa and submucosa have herniated through the circular

layer of the muscularis propria. True diverticula are rare. Diverticular disease refers to the broad range of symptoms and findings associated with diverticulosis and includes diverticulitis, an inflammatory process. Inflammation can be acute or chronic. Acute inflammation can present with a pericolic phlegmon, colon perforation leading to focal abscess formation, or generalized purulent or fecal peritonitis. Acute and chronic inflammation can cause fistulas between the involved bowel segment and the bladder, vagina, or skin. With chronic inflammation, a colonic stricture can develop, resulting in altered bowel habit or even obstruction.

Anatomy

Colonic diverticula are pulsion diverticula that occur in predictable sites on the bowel wall. Likewise, the pattern of segmental involvement of the colon and its progression are predictable. The sigmoid colon is at highest risk and is affected in 95% of patients. Involvement is isolated to the sigmoid colon in 30% to 60% of cases. Total colonic involvement occurs in 7% to 10% of cases.¹ The rectum is almost always spared. This segmental pattern of involvement is not observed in Asia, where 70% of pseudodiverticula are isolated to the right colon and cecum. The reason for this discrepancy is not known. Right colon pseudodiverticula are more likely to be solitary and tend to originate near the ileocecal valve.^{2–4} When true colonic diverticula develop, they

TABLE 69.1**INCIDENCE OF DIVERTICULOSIS IN WESTERN SOCIETY**

AGE	≤25 y	≤45 y	>60 y	>80 y
INCIDENCE	1%–2%	33%	40%	60%

are also more likely to be right sided; however, they are still much less common than pseudodiverticula of the right colon.

INCIDENCE

Diverticulosis is rare in nonindustrialized, less affluent societies. The French surgeon Alexis Littre is credited with first describing diverticulosis in 1700, but it wasn't until the mid-1800s that there were reports in the medical literature about the disease process and its treatment.⁵ The prevalence of diverticulosis increased after the industrial revolution and through this century. Even before 1940, it was recognized infrequently; retrospective reviews of colon radiographs and pathologic specimens record an incidence of 5% to 10%.⁶ An incidence of 46% in people 51 years of age and older was reported by Hughes from postmortem studies in 200 cadavers (Table 69.1).⁷ Incidence as a function of gender varies by study, some studies citing an increased incidence among men and others finding a higher incidence among women. It may be that the spectrum of complications and the age at which they develop are gender specific. The majority of people with diverticulosis remain asymptomatic; only 15% to 30% will go on to develop symptomatic disease.⁸ Of these, only 30% will require operative treatment.⁹ In the United States in 1998, 2.2 million cases of diverticular disease were treated at an estimated cost of \$2 billion.¹⁰

ETIOLOGY

- Neither the etiology of diverticulosis nor factors causing progression to symptomatic disease have been rigorously defined, but lack of dietary fiber, colonic dysmotility, and colonic structural abnormalities and age-related changes have all been implicated.

Structural/Anatomic Factors

In the colon, the outer, longitudinal layer of the muscularis propria is condensed in three longitudinal bands called the taenia coli. One of these runs along the mesenteric aspect of the colon; the other two are antimesenteric in location (Fig. 69.1). Mesenteric blood vessels encircle the colon and penetrate the

FIGURE 69.2. Postevacuation film of barium enema, demonstrating a giant colonic diverticulum (arrows) partially filled with barium. (Reproduced with permission from McNutt R, Schmitt D, Schulte W. Giant colonic diverticula. *Dis Colon* 1988;31:625.)

circular muscle in the intertaenial areas between the mesenteric taenia and the two antimesenteric taeniae. Pseudodiverticula develop at areas where these vessels pass through muscle.¹¹ Postmortem studies of the colon wall showed thinning of the circular muscle associated with early diverticula. Gaps in the circular muscle were observed with larger diverticula.⁷

In contrast to typical pseudodiverticula, giant colonic diverticula almost always arise from the antimesenteric border of the colon. They are assumed to be a complication of ordinary colonic diverticulosis, possibly developing after inflammatory narrowing of the neck of a pseudodiverticulum causes a ball-valve mechanism that entraps gas in the diverticulum, causing it to enlarge¹² (Fig. 69.2).

The observation of colonic diverticula in young patients with connective tissue disorders such as Marfan disease and Ehlers-Danlos syndrome raises the question of whether connective tissue genetic derangements play a role in diverticulosis development.^{13,14} Ordinary senescent connective tissue

FIGURE 69.1. Cross section of the colon illustrating the relation of diverticula to the blood vessels penetrating the circular muscle layer, the taeniae, and the appendices epiploicae.

change may be a factor as well. Cross-linkage of collagen fibrils in the colon wall increases with age, rising markedly after age 40, and appears to decrease compliance of the colon wall. In comparison with age-matched controls, this cross-linkage is exaggerated in patients with diverticulosis.¹⁵

Thickening of the colon wall in diverticulosis was originally attributed to muscle hypertrophy.^{11,16} This was disproven by histologic studies, but increased elastin deposition in the taeniae coli of patients with uncomplicated diverticulosis has been shown. The taeniae are shortened as a result, causing the circular muscle to be accorioned in the two intertaenial zones, the same areas where pseudodiverticula more commonly form.¹⁷ The functional significance of this is not known, but it has been speculated that muscle contractions may be stronger in these areas.

Motility Factors

Four unusual colonic motility patterns have been observed in the setting of diverticulosis: segmentation, high-pressure waves, slow wave motility pattern, and disorganized propulsive activity.

Segmentation. Painter et al. used cineradiography and manometry to study colonic motility and reported that when simultaneous haustral contractions occur in the same segment of colon, high pressure is generated in the intervening bowel, causing ballooning of the colon wall and distention of diverticula (Fig. 69.3).¹⁸

High-pressure Waves. High-pressure waves are independent of normal peristalsis and have an amplitude of 10 mm Hg in normal patients but have higher amplitude (up to 90 mm Hg) and longer duration in patients with diverticulosis.¹⁹

Slow Wave Motility Pattern. The normal slow wave pattern in the colon is altered in diverticular disease.^{20,21}

Disorganized Propulsive Activity. High-amplitude propulsive contractions occurred more frequently and were more

FIGURE 69.3. The role of segmentation in colonic physiology.

likely to be disorganized in patients with diverticular disease than normal subjects. Retropulsive contractions occurred more frequently in segments of colon with diverticulosis.²²

Other Factors

Other neurologic and chemical mediators of colonic motility may play a role in pseudodiverticula genesis. Vasoactive intestinal peptide levels are increased in the bowel wall of patients with diverticulosis.²³ Age-related vagal attrition has been postulated to contribute to colonic smooth muscle dysmotility.²⁴ Alterations of serotonin expression and function are noted after resolution of acute diverticulitis and may contribute to lasting symptoms.²⁵

Diet

Decreased dietary fiber is the most consistent factor associated with the high incidence of diverticulosis in Western populations. Painter and Burkitt first elucidated this connection after noting the striking disparity in incidence between British society and sub-Saharan populations. They measured colon transit time and stool weights in over 1,000 individuals in the United Kingdom and sub-Saharan Africa. The rise in incidence of diverticular disease coincident with the rise in refined food products in diets in the West was also noted.²⁶ Painter and Burkitt also reported improvement of diverticular disease symptoms in patients who increased dietary fiber and recrudescence of symptoms once fiber intake decreased again.²⁷ There is now a rising incidence of diverticulosis among previously low-risk populations in concert with changes to a Western-style diet as a consequence of economic development or immigration. Japanese immigrants to the United States acquire diverticulosis risk comparable to other Westerners, although the right-sided predominance of diverticulosis seen among Asians persists.^{5,28} The exact protective mechanism of stool bulk is not understood.

While the focus on dietary fiber has emphasized insoluble fiber, soluble fiber may also be relevant. Soluble fiber is processed by intestinal flora, which may in turn affect diverticulosis.^{28,29} Finally, despite the long-held admonition to avoid eating nuts and seeds, there is no evidence to support this recommendation.³⁰

Pathogenesis of Diverticulitis

The process by which a subset of people with diverticulosis develop diverticulitis has yet to be explained. Overwhelming inflammatory changes that develop with perforation or other complications of diverticulitis likely obscure subtle histologic details that might explain the pathogenesis of the disease. Traditionally, it has been postulated that mechanical obstruction by food or fecal material of a diverticulum leads to bacterial proliferation, gas, and toxin production in the occluded diverticulum, causing diverticulitis. However, the largely extra-colonic manifestations of diverticulitis (phlegmon, abscess, free perforation) suggest micro- or macroperforation as the inciting event, possibly as a kind of diverticular “blow-out” secondary to segmentation-type contractions or high-pressure waves. In recent years (and perhaps with the rising number of patients undergoing screening colonoscopy), peridiverticular inflammation has been identified, often in asymptomatic patients. *Diverticulitis-associated colitis* is of unrecognized clinical significance, partly because so many patients with these findings are asymptomatic and partly because the findings are not uniformly evident in patients requiring surgical therapy for diverticulitis. It has been suggested that low-grade inflammation could alter bowel motility and thereby contribute to diverticular perforation risk. Endoscopists are cautioned to avoid confusing diverticulitis-associated colitis with inflammatory bowel

disease. Probiotics and nonsteroidal anti-inflammatory medications are being explored as potentially protective agents.^{28,31,32}

DIAGNOSIS

Noninflammatory Diverticular Disease

Most patients with diverticulosis noted on barium study, colonoscopy, or abdominal CT scan are asymptomatic. In patients who have vague, crampy, left lower quadrant pain in the absence of fever, leukocytosis, or CT findings of focal inflammation, other causes of pain must also be considered. Additional symptoms reported may include nausea, flatulence, bloating, and change of bowel habit. The differential diagnosis includes colonic adenocarcinoma, constipation, inflammatory bowel disease, and irritable bowel syndrome. There are no peritoneal signs on examination, the rectal examination is unrevealing, and proctoscopy shows no inflammation. Postinflammatory neurogenic alteration has been postulated as a cause of visceral hypersensitivity.^{33–35} Nonspecific, mild mucosal inflammation and muscle spasm may also contribute. There is considerable overlap with irritable bowel syndrome. In addition to high-fiber modification of the diet and bulk-forming agents such as psyllium or flaxseed, anticholinergics, analgesics, and antibiotics can be prescribed to manage symptoms.

Hemorrhagic Diverticular Disease. Like bleeding from colonic angiodysplasia, diverticular hemorrhage is classically asymptomatic until presentation with lower gastrointestinal hemorrhage that can be massive. This differs from hemorrhage from inflammatory bowel disease or ischemic colitis where there are typically symptoms before bleeding begins. A foregut source of bleeding must be excluded by nasoenteric recovery of bilious,

nonbloody aspirate or upper endoscopy. Likewise, an anorectal source of bleeding must be excluded by examination. Localization of lower gastrointestinal hemorrhage of any cause is necessary to help guide appropriate colon resection should that be required. Although most cases of diverticular hemorrhage are self-limited, recurrence or failure of bleeding to stop spontaneously determines the need for resection. Colonoscopy, tagged red blood cell scan, or, if bleeding is brisk enough, angiography is used to localize bleeding (Fig. 69.4).

Giant Colonic Diverticula. Symptoms and signs of giant colonic diverticula may be noninflammatory (pain, bloating, nausea, vomiting, diarrhea, abdominal tenderness and mass) or inflammatory, resulting from perforation (pain, leukocytosis, fever, localized or generalized peritonitis).¹²

Inflammatory Diverticular Disease

The constellation of inflammatory signs and symptoms corresponds to the spectrum of inflammatory complications of diverticular disease. The Hinchey classification³⁶ categorized the severity of acute diverticulitis and has been modified to reflect refinements of diagnosis enabled by improved CT scan quality (Table 69.2).³⁷ The modified classification also includes manifestations of chronic inflammation such as fistula formation and stricture/obstruction.

Symptoms of acute diverticulitis include steady, left lower quadrant abdominal pain; fever; change in bowel habits (constipation or diarrhea); anorexia; nausea; vomiting; bloating; and urinary tract symptoms such as urinary frequency or retention. Examination will reveal left lower quadrant tenderness that may be appreciable only with deep palpation in stage 0 inflammation. In stage I or II inflammation, focal peritoneal

CLASSIFICATION

MODIFIED HINCHEY CLASSIFICATION

HINCHEY CLASSIFICATION	MODIFIED HINCHEY CLASSIFICATION	COMMENTS
	0 Mild clinical diverticulitis	Left lower quadrant pain, elevated white blood cells, fever, no confirmation by imaging or surgery
I Pericolic abscess or phlegmon	Ia Confined pericolic inflammation—phlegmon	
II Pelvic, intra-abdominal, or retroperitoneal abscess	II Pelvic, distant intra-abdominal, or retroperitoneal abscess	
III Generalized purulent peritonitis	III Generalized purulent peritonitis	No open communication with bowel lumen
IV Generalized fecal peritonitis	IV Fecal peritonitis	Free perforation, open communication with bowel lumen
Obstruction	Fistula colovesical/colovaginal/coloenteric/colocutaneous	
	Large- and/or small-bowel obstruction	

signs in the left lower quadrant are likely, and there may be a tender mass. Digital rectal examination may also reveal pelvic tenderness or a tender mass in the cul-de-sac. Generalized peritoneal signs would be expected for stage III or IV inflammation. Dehydration with earlier stages or evolving sepsis with later stages may cause tachycardia and hypotension. Leukocytosis is more likely with advancing stage of inflammation. The differential diagnosis includes perforated colon cancer, acute appendicitis, perforated peptic ulcer, acute ischemic colitis, pancreatitis, and flare of Crohn disease or ulcerative colitis. Normal serum amylase and lipase help exclude a diagnosis of pancreatitis. Imaging studies and endoscopy help to distinguish diverticulitis from the other diagnoses. However, active inflammation or contained perforation may limit the utility of rectal contrast CT, barium enema studies, and endoscopy in the acute setting. Distinguishing perforated colon cancer from diverticular disease can be especially challenging, even in the operating room.

Diverticular fistula formation represents internal drainage of an abscess (or external drainage in the case of colocutaneous fistulas). Approximately half of diverticular fistulas are colovesical fistulas. Women with colovesical or colovaginal fistulas have usually had a hysterectomy.^{38,39} Urinary tract infection symptoms, pneumaturia, and fecaluria are common complaints. Recurrent urinary tract infection in elderly men should raise concern for the presence of a colovesical fistula, which is often secondary to diverticular disease. Passage of feces or flatus from the vagina is a characteristic symptom of a colovaginal fistula. Colocutaneous fistulas are a rare complication of diverticular disease.

Thirteen percent of large-bowel obstructions are due to diverticular disease. The concurrent incidence of colon carcinoma in 7% of patients with symptomatic sigmoid diverticular disease confounds diagnosis and treatment.⁴⁰ CT scan is not as reliable for distinguishing these diagnoses as colonoscopy or contrast enema studies.

Right-sided diverticulitis frequently is confused with appendicitis, and misdiagnosis is common. The duration of symptoms is usually longer than appendicitis. Patients are usually older than those with appendicitis (late 30s or 40s) but younger than patients with typical left-sided diverticulosis (over 50 years of age).^{41,42}

Imaging and Diagnostic Studies for Diverticular Disease

Plain Radiographs. While seldom useful in the diagnosis of uncomplicated diverticulitis, a three-way abdominal series that includes an upright chest radiograph, an abdominal flat plate, and a left lateral decubitus view is useful for demonstrating free air. An ileus pattern or soft tissue mass may also be detected.^{43,44}

4 Computed Tomography Scan. CT scanning has revolutionized the diagnosis of acute diverticulitis and, sometimes, by way of percutaneous abscess drainage, its treatment. The accuracy of CT scans in the acute setting is central to the trend toward converting what formerly were surgical emergencies into elective, often single-stage operations. Intravenous and water-soluble oral and rectal enteric contrast should be administered. Water-soluble contrast is used to avoid barium peritonitis that may result if barium leaks from a perforated diverticulum into the peritoneal cavity.

A CT scan can reveal the presence and extent of diverticulosis, but its real strength is characterizing extracolonic inflammatory change. Signs of inflammation include colon wall thickening, pericolic fat stranding, or phlegmon formation. Pericolic abscess size and location can be detected (Fig. 69.5). Perforation is evidenced by free air; contained perforation may be identified by loculated extraluminal pericolic air. CT more accurately demonstrates diverticular abscesses and severity of inflammation than contrast enema studies.⁴⁵ Air in the bladder or contrast in the vagina may indicate the presence of a fistula (Fig. 69.6).

Rao et al. reported a misdiagnosis rate of up to 67% for diverticulitis in patients with abdominal pain managed without CT imaging.⁴⁶ An alternate diagnosis is suggested by CT scan in 45% to 58% of cases when diverticulitis is not found, including small-bowel obstruction, acute cholecystitis, appendicitis, gynecologic disease, and primary epiploic appendicitis.⁴⁷ Correct preoperative diagnosis of right-sided diverticulitis has also been enhanced by CT scanning.

Not only is CT useful for improving diagnostic accuracy, but also findings can predict failure of medical management or risk of secondary complications following medical management.

FIGURE 69.5. Sigmoid diverticulitis with pericolic abscess.

Ambrosetti et al. reported on 423 patients with acute diverticulitis on CT scan, categorizing them as having either moderate disease or severe disease. Criteria for moderate disease included localized wall thickening or inflammation of pericolic fat (modified Hinchey stage Ia; see Table 69.2). Severe disease included the presence of extraluminal air or contrast (contained perforation) or abscess (modified Hinchey stages Ib and II). Of the 42 patients who failed nonoperative management, 32 had severe disease. Twenty percent of those patients who were initially successfully managed nonoperatively developed secondary complications such as fistulas (median follow-up 46 months). They concluded that the presence of severe disease at the index episode predicted failure of nonoperative management and that there is a high risk of secondary complications after initial nonoperative management.⁴⁸

Ultrasound. Abdominal ultrasound has been emphasized in the European literature and is attractive as a strategy for limiting radiation exposure. However, its diagnostic limitations (user dependence, interference from overlying bowel gas, and decreased accuracy in obese patients) have precluded its widespread adoption in the United States. In skilled hands, it may have a role in image-guided percutaneous drainage of abscesses.⁴⁹

Contrast Enema Study (Barium Enema). Contrast enemas have been the “gold standard” test for the presence and anatomic distribution of diverticula (Fig. 69.7). For reasons cited earlier, CT scan has supplanted contrast enemas in the

FIGURE 69.7. Barium enema showing multiple diverticula of the colon.

5 acute setting. However, they are better than CT for helping distinguish colon cancer from diverticular obstruction, and contrast can also traverse narrowed areas of the colon impassable by an endoscope. While caution must be used in the acute setting to avoid perforation, these studies can be performed safely. Caveats are that contrast must be administered gently, water-soluble contrast should be used, and a single contrast study is performed in unprepared bowel to avoid the increased risk of perforation and fecal contamination with the administration of air. In chronic diverticular disease, the contrast enema can demonstrate stricture, angulation, and segmentation-type contractions. It can also be useful for the evaluation of fistulas.

Endoscopy. Like contrast enema studies, colonoscopy or flexible sigmoidoscopy can be used judiciously in the acute setting. It is particularly helpful in distinguishing malignancy from diverticular disease and can therefore help guide early management of acute presentations when malignancy as the cause of symptoms is being considered.

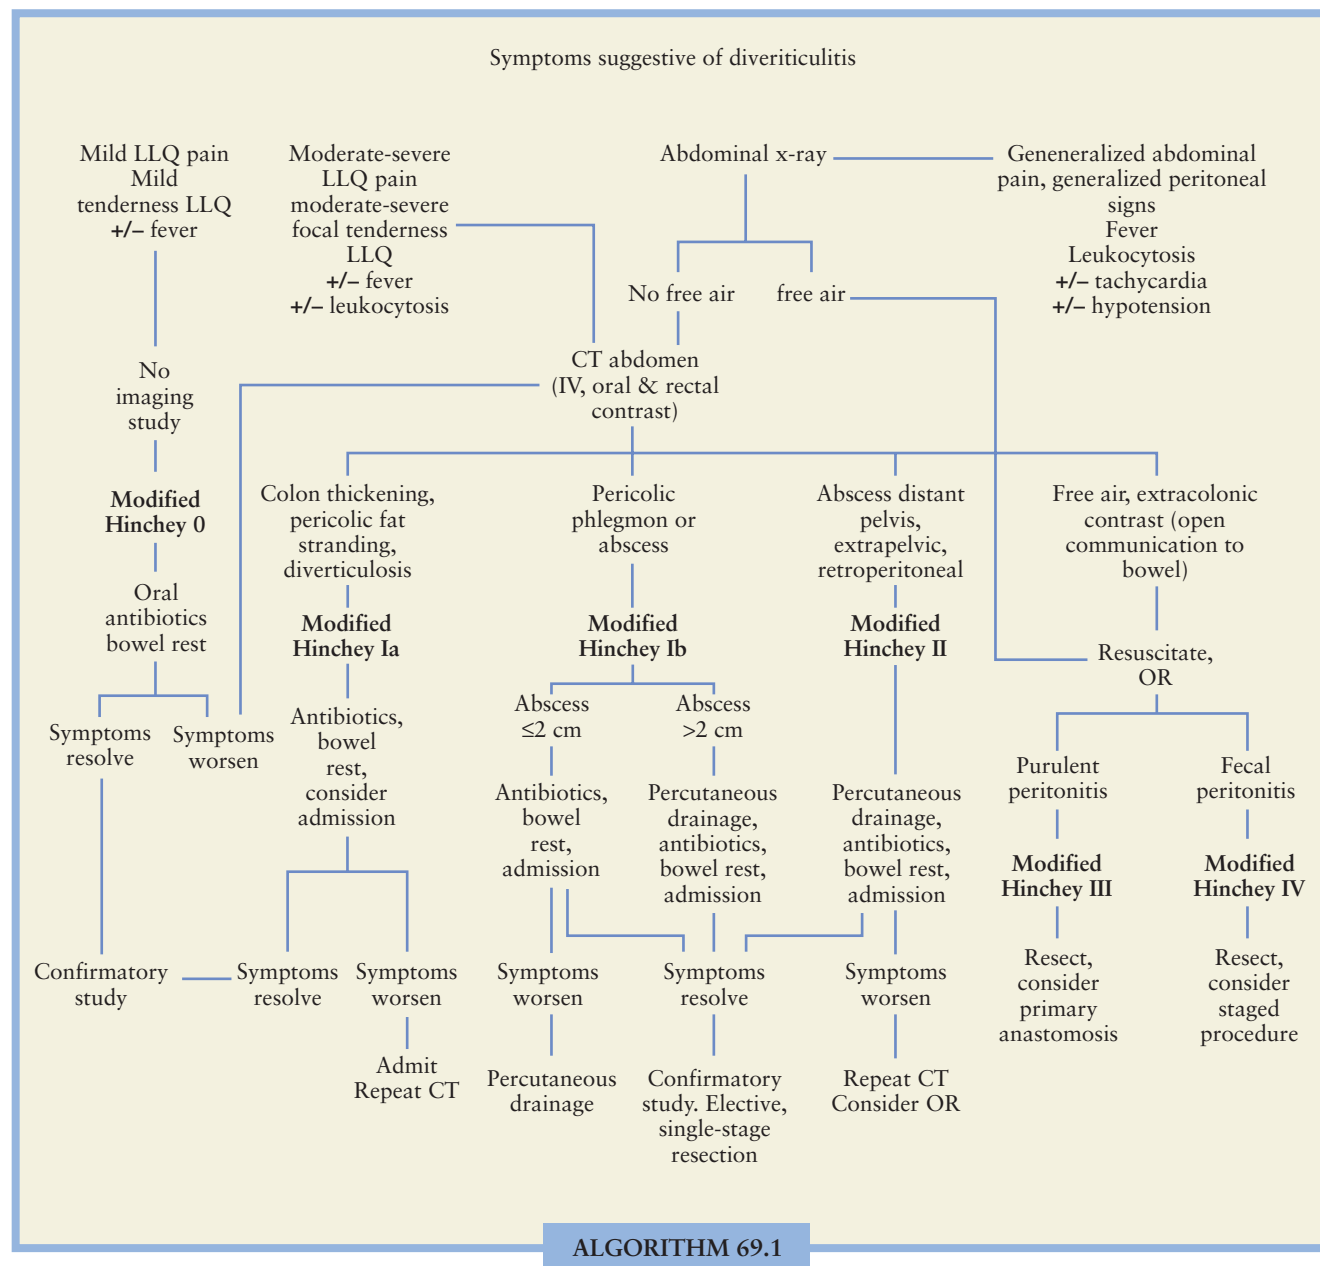

FIGURE 69.6. A: Computed tomography scan demonstrating air in the urinary bladder (arrow) in the presence of a colovesical fistula secondary to diverticulitis. B: Air in the urinary bladder (small arrow) in association with a paravesical inflammatory mass (large arrow). (Reproduced with permission from Sarr MG, Fishman EK, Goldman SM. Enterovesical fistula. *Surg Gynecol Obstet* 1987;164:2.)

ALGORITHM 69.1.

Cystoscopy. Cystoscopy can help diagnose colovesical fistulas. Although the fistula tract is usually difficult to see, focal hyperemia and inflammation may be noted. Symptoms of a colovesical fistula and air in the uninstrumented bladder on CT scan are usually sufficient for diagnosis.

TREATMENT

Symptomatic Diverticulosis

Fiber supplements and increased dietary fiber (goal 25 to 30 g/d) constitute the cornerstone of symptomatic diverticulosis treatment once diverticular stricture has been ruled out as the cause of symptoms. Stricture is an indication for elective segmental colectomy, typically a sigmoid colectomy to remove the area of stricture and the most dense region of diverticula.

Hemorrhagic Diverticular Disease

Diverticular hemorrhage stops spontaneously in more than 90% of patients; of these, 75% will not bleed again.⁵⁰ Patients who have a second episode of diverticular hemorrhage should undergo hemicolectomy of the involved portion of colon⁵¹ after localizing the site of hemorrhage endoscopically with a tagged red blood cell scan or with angiography, because these patients are likely to bleed again. If the site of bleeding cannot be determined definitively as left or right sided, a subtotal colectomy is the procedure of choice.⁵²

Diverticulitis

The treatment of diverticulitis typically parallels the Hinchey classification³⁶:

- **Stage I, confined pericolic abscess:** antibiotics and bowel rest
- **Stage II, pelvic or retroperitoneal abscess:** percutaneous abscess drainage
- **Stage III, purulent peritonitis:** resuscitation and urgent operation
- **Stage IV, feculent peritonitis:** resuscitation and urgent operation

Stage I diverticulitis is mild when patients can tolerate a diet, have no systemic symptoms (no fever, tachycardia, hypotension), and have no substantial peritoneal signs. The CT scan shows either minor pericolic fat stranding or wall thickening in the presence of diverticulosis. Outpatient management is usually appropriate for these patients. Broad-spectrum oral antibiotics are prescribed for 7 to 10 days, and patients start a clear liquid diet, advancing to a solid diet as symptoms resolve. If this is a first episode of presumed diverticulitis, an elective confirmatory study with either barium enema or colonoscopy is planned after inflammation has subsided. Progression of symptoms on this regimen warrants hospital admission and repeat CT scan may be necessary. The vast majority (70% to 100%) of patients with uncomplicated diverticulitis will recover without operative intervention. Although nearly a third will relapse, long-term fiber supplementation appears to reduce this risk.¹

6 Severe stage I inflammation is indicated by intolerance of diet, possible nausea and vomiting, fever, chills, and peritoneal signs on examination, which are often focal. The CT scan may show a phlegmon or contained pericolic abscess. These patients are admitted to the hospital for parenteral broad-spectrum antibiotics. They are placed on bowel rest, intravenous fluids are administered, and if nausea and vomiting are major symptoms, a nasogastric tube may be placed. Analgesia is provided but limited to enable evaluation of symptom progression. In addition, since narcotics are known to cause strong, nonpropulsive sigmoid colon contractions, their use in patients with diverticulitis should be minimized. Small (<2 cm) pericolic abscesses may resolve with intravenous antibiotics; larger contained abscesses will likely require percutaneous drainage with CT (or possibly ultrasound) guidance.^{1,53} If a smaller abscess is treated initially with antibiotics only but symptoms fail to improve, percutaneous drainage should be considered. Progression of symptoms despite percutaneous drainage of an abscess usually indicates the need for surgery. Historically, 10% to 25% of patients requiring hospitalization for treatment of diverticulitis will not improve or will worsen with medical management alone; overall, 30% of hospitalized patients will require an operation. Those patients who recover from an initial episode of complicated diverticulitis (contained perforation or abscess) should be considered for single-stage, elective segmental colectomy after the resolution of acute inflammation.⁵⁴ As will be discussed further, minimally invasive surgical techniques are increasingly being used with good outcomes in these patients.

7 Patients who fail nonoperative management of diverticulitis or who present with purulent or feculent peritonitis require operative treatment. The goal of surgery in these patients—especially if they are toxic, developing multisystem organ failure, or hemodynamically unstable—is to resect the perforation and make a stoma. This defines a Hartmann procedure, in which the offending segment of colon is resected, a proximal stoma is constructed, and the distal colon and/or rectum are closed and left in the pelvis. The distal remaining segment of colon and rectum are referred to as a Hartmann pouch. This approach was favored for many years because it is quick and simple and there is no chance of anastomotic leak. However, 30% to 50% of patients treated in this way never undergo reversal of the stoma, and when they do, the complication rate is high (major complications in 5% to 25%, anastomotic leak in 2% to 30%).^{55,56}

Despite these problems, this is still the procedure of choice in unstable patients. However, in the more stable patient who requires an urgent operation because of generalized diverticular peritonitis on presentation or failure of nonoperative management, the goal should be resection with primary anastomosis and creation of a diverting stoma, usually a loop ileostomy. The anastomotic leak rate in patients with free diverticular perforation who undergo a single-stage operation acutely is 13%.⁵⁷ While diverting ileostomy or colostomy upstream from a primary anastomosis does not prevent an anastomotic leak, it lessens the consequences of a leak by diverting the fecal stream from the area, preventing potentially devastating gross fecal soilage through the defect.

Obstruction

Complete obstruction from diverticular disease is unusual. Partial obstruction resulting from edema, spasm, and inflammation is more common. The differential diagnosis includes cancer and inflammatory bowel disease. Medical treatment and elective resection are usually successful. Rarely is the placement of a colonic stent necessary, but it may be used to allow for bowel preparation before a single-stage resection with primary anastomosis. A diverting stoma may be necessary to relieve obstruction and enable completion of the workup and treatment before definitive resection. If perforation has resulted from obstruction, even when the distinction between obstructive cancer and diverticular obstruction cannot be made, the perforated segment should be resected and diverting end-colostomy performed. If this is a right-sided process in a relatively stable patient, primary anastomosis and diverting loop ileostomy can be considered.

Fistula

The presence of a fistula usually obviates the need for an emergency operation because the abscess has in effect spontaneously drained internally. A single-stage operation should be planned. The bladder side of a colovesical fistula is usually disrupted bluntly at the time of colon resection. No repair of the bladder is needed unless there is a visibly patent opening at the transected fistula tract site. A urinary drainage catheter is left in place for 7 to 10 days after surgery.³⁸ A cystogram can be done to verify closure of the tract opening and can facilitate discharge without an indwelling catheter following laparoscopic resection, which is often earlier than after open procedures. It is not necessary to leave a pelvic drain at the time of resection. Likewise, fistula tract openings to the vaginal cuff do not require closure. At most, omentum can be draped into the pelvis to separate the fresh colorectal anastomosis from the opening on the vagina.

Giant Colonic Diverticulum

Treatment is surgical resection of the involved segment of colon. Planned electively, a single-stage operation is indicated. Once perforated, the decision process parallels common diverticulitis, preference being given to resection with primary anastomosis and diverting loop stoma in the stable patient.

MANAGEMENT

Operative Strategies

The most important advance in the surgical management of diverticular disease besides trying to convert staged, emergency

operations into elective, single-stage operations is the introduction of minimally invasive surgical techniques. No matter what the approach, certain challenges face the surgeon operating for diverticular disease. Inflammation distorts the anatomic planes. Dense fibrosis and adhesions impede sharp dissection and make it difficult to get good traction and countertraction that enable dissection. Inflammatory adhesions interfere with visualization and sometimes even palpation of anatomic structures.

Key concepts apply to both laparoscopic and open procedures. The goal is not to remove every diverticulum but rather to resect the area of inflammation or complication. The proximal resection line should be at soft, pliable bowel. The distal resection line must be at the top of the rectum demarcated by spaying of the bunched longitudinal muscle fibers (taenia coli) into the continuous longitudinal, outer layer of the rectal muscularis propria. The point of transection is almost never below the anterior pelvic peritoneal reflection. The splenic flexure should almost always be mobilized to facilitate creation of a tension-free colorectal anastomosis. The anastomotic site itself must be free from diverticula, which can be difficult in the patient with dense, pandiverticulosis. Manual, pinch dissection (or “finger fracture”) techniques are used to separate structures and divide areas of fibrosis and thick adhesions. Dissection commences away from the focus of inflammation, usually proximal to it. The left ureter should be identified as early as possible and before transecting major vessels or the colon. In the setting of severe inflammation in the left lower quadrant or pelvis, it can be very helpful to mobilize and divide the proximal bowel as an initial operative maneuver. Likewise, when dense inflammation makes the standard, lateral-to-medial mobilization of the sigmoid difficult, a medial-to-lateral approach can sometimes provide access to less inflamed tissues. While typically not needed, when a preoperative CT scan shows dense inflammation in proximity to the left ureter, placement of ureteral stents can help with ureteral identification and protection during dissection. Whether using open or laparoscopic techniques, an elective operation should be deferred for 4 to 6 weeks after the last episode of inflammation so that acute inflammatory changes do not interfere with either the dissection or the construction of a safe colorectal anastomosis.⁵⁸

There is growing experience with laparoscopic resection of even complicated diverticular disease. A meta-analysis comparing laparoscopic to open diverticulitis resections concluded that the laparoscopic patients had lower infection rates (overall and wound); decreased pulmonary, gastrointestinal, and cardiovascular complications; and a shorter time to recovery of bowel function and hospital discharge. Although studies in the meta-analysis included acute and chronic indications for surgery and complicated as well as uncomplicated diverticulitis in both groups, the authors cautioned that the retrospective nature of the reviewed studies introduced selection bias.⁵⁹ When laparoscopic resections for diverticular disease are performed early (2 to 16 days after hospital admission), the conversion rates are higher than when surgery is delayed (more than 6 weeks).⁶⁰ Hand-assisted minimally invasive operations may offer significant benefit compared to pure laparoscopic surgery for diverticular disease, showing lower conversion rates, shorter operative times, and no compromise of the speedy recovery associated with fully laparoscopic operations.⁶¹

Elective Surgery

Several observations form the basis of recommendations for elective resection following episodes of diverticulitis. Forty percent of diverticulitis patients admitted to the hospital will develop a complication, 23% following a single episode and 58% following two episodes. Thirty to 45% of patients hospitalized for diverticulitis will have another flare, usually within 5 years (90%). Among patients hospitalized a second time,

only 10% remain symptom-free.^{62–64} Mortality doubles with a second flare. The classic indications for elective resection include two or more episodes of *documented* diverticulitis, a single episode of complicated diverticulitis (modified Hinchey stage Ib or II), one documented episode in an immunocompromised patient, one documented episode in a young patient (40 to 50 years old), and an inability to exclude cancer as the cause of the signs and symptoms.

Practice parameters outlined by the American Society of Colon and Rectal Surgeons note that most patients who present with complicated diverticulitis do so at their first episode, so operating on patients with uncomplicated episodes of diverticulitis may not reduce the risk of emergency surgery and mortality. “The age and medical condition of the patient, the frequency and severity of the attack(s), and whether there are persistent symptoms after the acute episode” may be better determinants of recommendation for elective resection.¹ Complications develop often enough after successful medical management of complicated diverticulitis to warrant recommending elective resection.⁴⁸ Kaiser et al. reported that 41% of patients treated with percutaneous drainage of a diverticular abscess will later develop severe sepsis.³⁷

It has been noted that the incidence of diverticular disease has steadily increased among young people, from 12% in 1969⁶⁵ to 20% in 1998⁶⁶ to 54% in a study of young and obese American patients in 2006.⁶⁷ Traditionally, elective colon resection was recommended for young people (age younger than 50 years) after one documented episode of uncomplicated diverticulitis. This recommendation was based on the belief that diverticular disease is more virulent in young patients. However, data are conflicting in this regard. There have been reports of young patients’ increased risk of complicated disease at presentation, increased frequency of recurrences (in the same time period as older patients, not as a function of longevity), and higher risk of needing emergency surgery and colostomy. Recommendation for elective resection following a single episode of uncomplicated diverticulitis in patients younger than 50 years of age was motivated by an interest in avoiding a colostomy and avoiding major morbidity and mortality. In view of conflicting data and adoption of technical strategies for avoiding end-colostomies in all patients, Nelson et al. have suggested following the same guidelines that are used for older patients.^{54,68–74}

Immunocompromised patients are more likely to fail medical management and must be watched closely since the manifestations of failure may be more subtle than in immunocompetent patients. Transplant patients, those on steroids or chemotherapy, diabetics, and dialysis patients are at risk. Elective resection in anticipation of transplant is also considered in some patients with diverticular disease. Interestingly, human immunodeficiency virus (HIV)-positive patients with normal CD4 counts appear to behave as if they were immunologically normal with respect to the incidence of diverticulitis and its clinical course. Since HIV infection has principally been an illness of younger people, most studies of diverticulitis have not included a large number of HIV-positive patients.⁷⁵ That may change as longevity improves with current antiretroviral regimens.

SUMMARY

Diverticular disease is common and includes a spectrum of presentations and anatomic locations, favoring the left colon in Western societies. The etiology is likely multifactorial, with a low-residue diet being a common factor. The CT scan has dramatically improved diagnostic accuracy and helped with treatment planning. Treatment often parallels the Hinchey stage, particularly the modified Hinchey classification. Surgical treatment has evolved to favor medical management and image-guided percutaneous drainage of abscesses when feasible to convert surgical-emergency staged procedures into either

single-stage procedures or procedures with primary anastomosis and diverting loop stoma. The distinction of complicated diverticular disease and colon cancer can be difficult, but early contrast enema studies or colonoscopy can be safely performed and are the most helpful diagnostic procedures in this setting. The indications for elective resection following successful medical management of diverticular disease are being reconsidered, and it is becoming clear that elective sigmoid resection for diverticular disease should be offered to avoid recurrent symptoms, not primarily to avoid free perforation and the need for an emergent colostomy. Minimally invasive surgery is state of the art, and the hand-assisted techniques are particularly useful for elective diverticular disease resections.

CHAPTER 70 ■ ANORECTAL DISORDERS

BARD C. COSMAN, ARDEN M. MORRIS, SANTHAT NIVATVONGS, AND ROBERT D. MADOFF

KEY POINTS

- 1 The most common manifestation of hemorrhoids is painless, bright red rectal bleeding associated with bowel movements.
- 2 A high-fiber diet with fiber supplements reduces symptoms of hemorrhoids and is ideal for first- and second-degree hemorrhoids.
- 3 Rubber band ligation is suitable for symptomatic first- and second- and some third-degree internal hemorrhoids that do not respond to bulk-forming agents.
- 4 Hemorrhoidectomy is required in only a few patients with symptomatic hemorrhoids. It should be considered when the hemorrhoids are mixed internal and external, are severely prolapsed through the anus, or are complicated by associated pathology, such as ulceration, fissures, fistulas, large hypertrophied anal papillae, or extensive skin tags.
- 5 Rectal prolapse is a rectal intussusception that extends beyond the anal verge. Fit patients are best treated with transabdominal rectopexy. Patients with significant medical comorbidities are best treated using a perineal approach.
- 6 Anal fissure is an ischemic ulcer in the lower portion of the anal canal; its treatment, both medical and surgical, involves relaxing the internal anal sphincter.
- 7 Infection of the anal glands is the origin of perianal abscesses.
- 8 Anal fistula is a chronic form of perianal abscess, spontaneously or surgically drained, in which the tract persists, with an internal opening at the dentate line and an external opening on the perianal skin.
- 9 Anal condylomata acuminata are caused by human papillomavirus, as are anal intraepithelial neoplasia and anal cancers.
- 10 Palpable lesions of the anal canal are not hemorrhoids and may be cancers; examination under anesthesia and biopsy allow for correct diagnosis.

ANATOMY AND PHYSIOLOGY

The Rectum

The rectum, the terminal portion of the large bowel, extends from the level of the sacral promontory to the level of the levator ani muscle and is approximately 15 cm in length. The rectum differs from the colon in that the outer, longitudinal muscular layer is continuous, as opposed to condensing into the three taeniae of the colon. The rectum has two or three lateral curves that form submucosal folds in the lumen, known as the *valves of Houston*. The posterior aspect of the rectum is devoid of peritoneum and adjoins the mesorectum, which is immediately anterior to the presacral fascia. The presacral fascia is a strong, endopelvic fascia that covers the entire anterior surface of the sacrum and also covers the underlying vessels and nerves. At about the level of S4, the presacral fascia runs anteriorly and inferiorly and attaches to the rectum, an area known as the *rectosacral fascia* or *Waldeyer ring* (Fig. 70.1).¹ This fascia must be incised for full mobilization of the rectum during abdominoperineal resection or extended low anterior resection. Peritoneum covers the upper two thirds of the rectum anteriorly and the upper one third of the rectum laterally; the lower third of the rectum is entirely devoid of peritoneum. The level of the anterior peritoneal reflection is variable, but most often is 6 to 8 cm from the anal verge. The extraperitoneal portion of the rectum is surrounded by endopelvic fascia. On the anterior surface, this is called the *Denonvilliers fascia*

and lies just posterior to the vagina in females and the seminal vesicles in males.

The Anal Canal and Sphincters

The anal canal, about 4 cm in length, is the transitional organ that extends from the rectum, as it passes through the levator ani or pelvic floor, traverses the anal verge, and extends to the hair-bearing skin of the anal margin. The muscular wall of the anal canal, continuous with the circular smooth muscular layer of the rectum, is thickened and forms the internal anal sphincter. The anal canal is wrapped by the striated external anal sphincter muscle inferiorly. The puborectalis muscle loops around the anorectal junction posteriorly, forming a U-shaped sling that originates on the posterior pubic bones. Although there is functional continuity between the puborectalis and external sphincter, magnetic resonance imaging studies indicate that the deepest portion of the external anal sphincter is separated from the puborectalis by a layer of fat.² The elliptical external sphincter muscle extends from the coccyx, where its origin is called the *anococcygeal ligament*, to the perineal body, encircling the anal canal (Fig. 70.2).

At the upper portion of the anal canal, called the *anorectal ring*, the internal sphincter is discretely palpable, and the puborectalis muscle can be palpated digitally. From the level of the anorectal ring distally and between the internal and external sphincter muscles, the longitudinal muscle coat of the rectum

FIGURE 70.1. Fascial attachments of the rectum.

is joined by fibers of the levator ani and puborectalis to form the conjoined longitudinal muscle (Fig. 70.3). These muscle fibers traverse the external sphincter to insert in the skin of the anal verge as the *corrugator cutis ani*, which causes wrinkling of the anal verge. This mixed smooth/striated longitudinal anal muscle may play a significant role in anal function, unifying or coordinating the two sphincters.³

At about the midpoint of the anal canal, roughly 2 cm from the anal verge, there is an undulating demarcation called the *dentate* or *pectinate line*, meaning toothed or comblike line. Longitudinal folds of the mucosa above the dentate line are known as the *columns of Morgagni*. For a distance of about 1 cm above the dentate line, the epithelial lining may be columnar, transitional, or stratified squamous epithelium; this area is referred to as the *transitional* or *cloacogenic zone*. The internal hemorrhoidal vascular plexus lies deep to the mucosa at this location. The area above the transitional zone is lined by columnar epithelium, and the area below the dentate line is lined by squamous epithelium (Fig. 70.3).

The ‘surgical’ anal canal extends from the anorectal ring to the anal verge. The term *anoderm* describes the skin of the anal verge: non-hair-bearing skin distal to the dentate line, but proximal to the hair-bearing skin of the anal margin. The perianal skin (anal margin) extends from the lateral border of the anal verge, where normal hair-bearing skin starts, to 5 to 6 cm from the anal verge.

Pelvic Floor Muscles

The pelvic floor consists of the levator ani muscle and the coccygeus muscle. The levator ani is a broad, thin muscle that forms the floor of the pelvic cavity and is innervated by the fourth sacral nerve and the pudendal nerve. This muscle has two distinct parts, iliococcygeus and pubococcygeus, and regions of the pubococcygeus are further named puborectalis, pubovaginalis, and puboprostaticus.

FIGURE 70.2. Arrangement of the external sphincter muscles.

FIGURE 70.3. Anatomy of the anal canal.

The levator ani arises from the body of the pubis, the ischial spine, and the tendinous arch of the obturator fascia that runs between them, and it inserts on the last two segments of the sacrum, the coccyx, and the *anococcygeal raphe*, which is a decussation with fibers from the opposite site (Fig. 70.4). In the standing position, the puborectalis contraction creates an anorectal angle of nearly 90 degrees, while the levator ani supports the viscera. During defecation, the puborectalis relaxes, straightening the anorectal angle and creating a straight path for evacuation.

Perianal and Perirectal Spaces

Surrounding the anorectum are several potential spaces that are normally filled with areolar tissues and fat, but which can harbor abscesses. The *perianal space* immediately surrounds the anus. Laterally, the perianal space is continuous with the subcutaneous fat of the buttocks. Medially, it is bounded by the anal verge. The *ischioanal fossa* is a triangular region inferior to the levator ani muscle, bounded medially by the external sphincter and laterally by the ischium and obturator internus (Fig. 70.5). The fatty, areolar ischioanal fossa also contains the inferior rectal vessels and lymphatics. The *deep postanal space* (of Courtney) connects the ischioanal space on each side

posteriorly and lies between the levator ani muscle superiorly and the anococcygeal ligament inferiorly (Fig. 70.6). The deep postanal space is an important pathway in the formation of abscess; spread from one ischioanal fossa to the other may result in a *horseshoe abscess*, the 'horseshoe' being open anteriorly, where there is no communication between the ischioanal fossae. The *intersphincteric space* lies between the internal and external sphincters. It is continuous with the perianal space below and extends above into the supralelevator space. The *supralelevator spaces* are situated on each side of the rectum above the levator ani muscle (Fig. 70.5). The supralelevator spaces communicate posteriorly and may allow spread of infection cephalad into the retroperitoneum (Fig. 70.6).

Arterial Supply of the Rectum and Anal Canal

The superior rectal (hemorrhoidal) artery is the continuation of the inferior mesenteric artery and descends posterior to the rectum, where it bifurcates to supply the rectum and the upper anal canal (Fig. 70.7). The middle rectal (hemorrhoidal) arteries arise from the internal iliac artery on each side and enter the lower rectum anterolaterally. The inferior rectal

FIGURE 70.4. Muscles of the pelvic floor.

FIGURE 70.5. Anatomy of the perianorectal spaces (anteroposterior view).

(hemorrhoidal) arteries arise from the internal pudendal artery, a branch of the internal iliac artery, and traverse the ischioanal fossa on each side to supply the anal sphincter muscles. There are abundant intramural anastomoses between the superior, middle, and inferior rectal arteries, making rectal ischemia exceedingly rare, even after substantial devascularization.

Venous Drainage of the Rectum and Anal Canal

Venous return from the rectum and anal canal joins both portal and systemic systems (Fig. 70.8). The superior rectal (hemorrhoidal) vein drains the rectum and upper anal canal into the portal system via the inferior mesenteric vein. The middle rec-

tal (hemorrhoidal) veins drain the lower rectum and the upper anal canal into the internal iliac veins. The inferior rectal (hemorrhoidal) veins drain the lower anal canal into the internal pudendal veins, which join the internal iliac veins. Each vein follows the correspondingly named artery. Portal-systemic shunts may thus occur in the rectum as they do in the esophagus, and bleeding rectal varices—not the same as hemorrhoids, and located in the rectum rather than the anus—may result.

Lymphatic Drainage of the Rectum and Anal Canal

Lymph from the upper and middle rectum ascends adjacent to the superior rectal artery to inferior mesenteric lymph nodes.

FIGURE 70.6. Anatomy of the perianorectal spaces (lateral view).

FIGURE 70.7. Arterial supply of the rectum and anal canal.

FIGURE 70.8. Venous drainage of the rectum and anal canal.

FIGURE 70.9. Lymphatic drainage of the rectum.

The lower rectum drains likewise to inferior mesenteric nodes, but also laterally to internal iliac nodes (Fig. 70.9). Lymphatics from the anal canal above the dentate line may drain to inferior mesenteric nodes, or laterally, to internal iliac nodes. Lymph from the anus below the dentate line usually drains to inguinal nodes, although it can also drain to inferior mesenteric or internal iliac nodes if obstruction occurs in the primary drainage (Fig. 70.10). Lymphatic drainage of the perianal skin is entirely to the inguinal nodes.

Nerve Supply of the Rectum and Urogenital Organs

Sympathetic and parasympathetic nerves of the autonomic system supply the anus and rectum and also supply the adjacent urogenital organs. Nerve trunks close to the rectum are prone to injury during rectal mobilization unless specific precautions are taken.

Sympathetic fibers to the rectum are derived from the first three lumbar segments of the spinal cord. Sympathetic fibers pass through ganglionated sympathetic chains before forming the preaortic plexus. Preaortic fibers extend below the bifurcation of the aorta to form the hypogastric plexus or the presacral nerve (Fig. 70.11). The plexus thus formed divides into left and right branches, which are joined by the parasympathetic nerves.

The pelvic parasympathetic nerve supply is from pelvic splanchnic nerves (nervi erigentes), which originate from the second, third, and fourth sacral nerve roots. These nerves, joined by

FIGURE 70.10. Lymphatic drainage of the anal canal.

sympathetic fibers, form the pelvic plexus. The pelvic plexus is encased in the lateral attachments of the rectum, just superior to the levator ani (Fig. 70.11). From the pelvic plexuses, both types of autonomic nerve fibers distribute to urinary and genital organs.

In women, sympathetic fibers from the hypogastric plexus are directed toward the uterosacral ligament, close to the rectum. In men, fibers from the hypogastric plexus pass immediately adjacent to the anterolateral wall of the rectum in the retroperitoneal tissue.

The pelvic plexus gives rise to the periprostatic plexus, an important subdivision that is essential to sexual function in men. Both parasympathetic and sympathetic systems are involved in sexual function. Parasympathetic activity leads to erection, and a complex coordination between sympathetic, parasympathetic, and somatic systems produces ejaculation. Depending on which nerves are damaged during proctectomy, deficiencies may include incomplete erection, lack of ejaculation, retrograde ejaculation, or total impotence.⁴ In women, the consequences of pelvic nerve injuries are poorly understood, but better definition of sexual-dysfunction states will likely lead to a similar list of postoperative complications.⁵

The pudendal nerve arises from the sacral plexus (S2–S4). Leaving the pelvis through the greater sciatic foramen, it reenters via the lesser sciatic foramen and travels in the pudendal canal in the lateral wall of the ischioanal fossa. Its branches include the inferior rectal (anal) nerve, perineal nerve, and dorsal nerves of the penis or clitoris. The pudendal nerve is anatomically protected from injury during mobilization of the rectum. Since sensory stimuli from the penis and clitoris are pudendally mediated, they are preserved after proctectomy.

FIGURE 70.11. Sympathetic and parasympathetic nerve supply of the rectum.

Nerve Supply of the Anal Canal

Motor Innervation. Both sympathetic and parasympathetic nerves supply the internal anal sphincter, which maintains tonic contraction until the complex and coordinated process of defecation allows it to relax. The external sphincter is supplied by the inferior rectal (anal) branch of the pudendal nerve and the perineal branch of the fourth sacral nerve.

Sensory Innervation. The sensory supply of the anal canal comes from the inferior rectal nerve, a branch of the pudendal nerve. The epithelium of the anal canal is profusely innervated with sensory nerve endings, especially at and just distal to the dentate line. Painful sensations in the anal canal can be felt up to 1.5 cm proximal to the dentate line, a fact one must keep in mind when treating internal hemorrhoids in the unanesthetized patient. Such treatment relies on the lack of somatic sensation above the dentate line, so one should test for sensation before banding, injecting, or coagulating in that area.

Physiology of the Anorectum

Sensation of the Anorectum. Complete anal continence cannot be achieved unless the subject can sense material in the rectum and can discriminate the contents by type (gas or feces). The receptors responsible for appreciation of rectal fullness and impending evacuation lie outside the anorectum, probably within the levator ani muscle. The anal canal epithelium is rich with sensory nerve endings, but although this sensitive area helps one discriminate between flatus and stool, it is not a critical factor in preserving anal continence.

Mechanism of Anal Continence. Stool can accumulate in the rectum for hours or days before triggering the urge to defecate. The ability of the rectum to retain stool is called reservoir continence. Continence is partly created by the puborectalis muscle, which functions as a sling, pulling the anal canal forward and creating an anorectal angle of 80 to 90 degrees. This angle, maintained by the continuous tonic activity of the puborectalis muscle, is effective in preventing stool from entering the anal canal. Within the anal canal, the hemorrhoidal pillars contribute to continence by functioning as submucosal anal cushions, accounting for about 15% of anal resting pressure.⁶

The autonomically innervated internal anal sphincter is not subject to voluntary control. Under normal circumstances, tonic contraction of this muscle maintains approximately 55% of the anal canal resting pressure in a “high-pressure zone.” The somatically innervated external sphincter contributes about 30% to resting anal pressure, and it accounts for all of the increase in pressure during voluntary contraction (squeeze pressure). The high resting pressure in the anal canal acts to preserve continence, preventing leakage of stool and gas.

When the rectum is distended, pressure receptors in the puborectalis stimulate the rectoanal inhibitory reflex. This reflex causes internal anal sphincter relaxation and external anal sphincter contraction, allowing the sensory epithelium of the anal canal to ‘sample’ anal canal contents without leakage. This allows discrimination of the nature of the material. If rectal distention is maintained—that is, defecation is deferred—the rectal vault relaxes, decreasing the rectal pressure in an *accommodation response*. Incontinence may occur with an abrupt and marked distention of the rectum that inhibits external sphincter contraction. Although volitional contraction

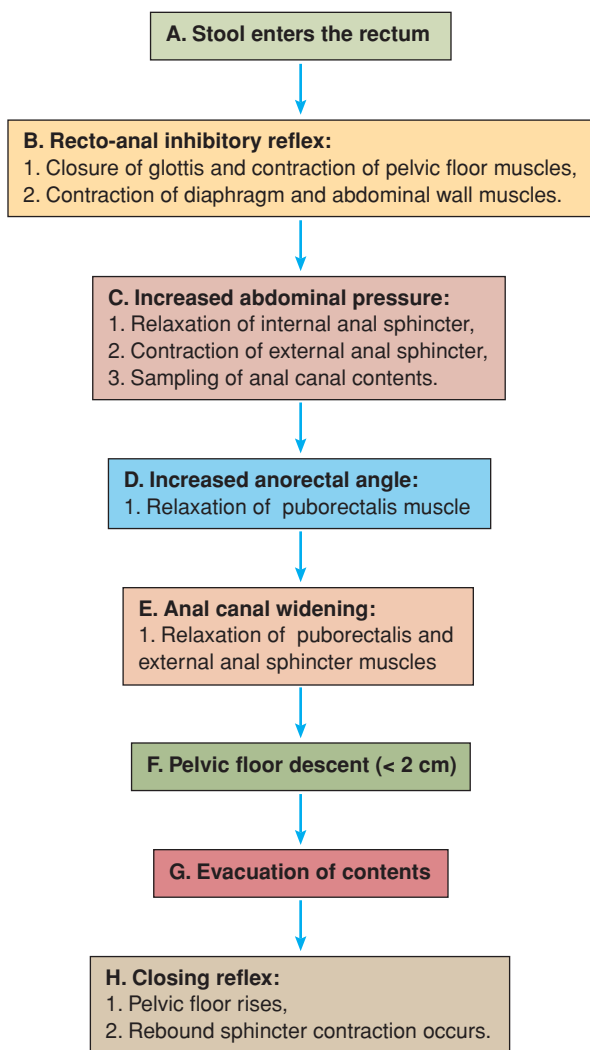

FIGURE 70.12. Mechanics of defecation.

of the external sphincter can be sustained only for short periods, it is the most important mechanism of voluntary continence and the last line of defense in the continence system.

Mechanism of Defecation. Defecation is a complex process that involves both reflex response and voluntary action (Fig. 70.12). When the anal canal is deemed to have solid contents and a decision to defecate is made, the subject assumes a squatting or sitting position to help straighten the anorectal angle and performs a Valsalva maneuver. With the glottis closed, there is contraction of diaphragm, abdominal wall muscles, and pelvic floor muscles, all increasing abdominal pressure. The puborectalis relaxes, resulting in further straightening of the anorectal angle, and the pelvic floor descends slightly. The external anal sphincter is relaxed, and the anus and rectum are evacuated. On completion of evacuation, the pelvic floor rises and sphincters contract once more in a closing reflex. The external sphincter is contracted voluntarily, and the normal postural tone of the internal sphincter and puborectalis is restored.

BENIGN ANORECTAL DISEASE

Hemorrhoids

In the upper anal canal, superior to the dentate line, the anal (hemorrhoidal) cushions are composed of three submucosal

TABLE 70.1 CLASSIFICATION

GRADING OF INTERNAL HEMORRHOIDS

DEGREE	DESCRIPTION
First	Hemorrhoids bleed but do not prolapse
Second	Hemorrhoids prolapse on straining but reduce spontaneously
Third	Hemorrhoids prolapse and require manual reduction
Fourth	Prolapsed hemorrhoids cannot be manually reduced

pillars of sinusoids within connective tissue, commonly at the left lateral, right anterior, and right posterior positions. The pathologic term *hemorrhoid* is used to describe the downward displacement of the cushion along with dilation of the contained sinusoids and sometimes bleeding from the arterial, venous, or sinusoidal portions.⁷ Thus, hemorrhoids develop when the supporting tissues of the anal cushion deteriorate, or as a result of excessive downward pressure, as in prolonged straining at stool or pregnancy.

Classification. *External hemorrhoids* are defined by their original location below the dentate line, i.e., they must be covered with squamous epithelium. Most external hemorrhoids are the external concomitants of internal hemorrhoids, so apart from thrombosis, there is practically no such thing as an independent external hemorrhoid problem. *Thrombosed external hemorrhoids* are intravascular clots in the sinusoids or venules of the external hemorrhoids. *Internal hemorrhoids* are the anal cushions defined by their original internal location—above the dentate line, thus covered with the epithelium of the transitional zone—that are prolapsing and/or bleeding.⁸ For practical purposes, internal hemorrhoids are graded according to the degree of prolapse (Table 70.1).

Clinical Manifestations. Popular wisdom notwithstanding, the common complaints of burning, itching, swelling, and pain usually are not from internal hemorrhoids but result from other distinct conditions such as pruritus ani, anal abrasion, anal fissure, thrombosed external hemorrhoids, or prolapsed anal papilla. The most common manifestations of internal hemorrhoids are painless, bright red rectal bleeding associated with bowel movements, and prolapse of tissue with defecation. Symptoms are aggravated by, but never the cause of, constipation and diarrhea. With significant hemorrhoids, the patient commonly describes blood dripping into the toilet bowl. A feeling of incomplete evacuation is also common. In chronic prolapse, exposed transitional mucosa often causes perianal skin irritation and mucous staining on underclothes. Congestion of external hemorrhoids can cause discomfort, and the related skin tags can be a hygiene problem. Except in the presence of obvious thrombosis, pain is rarely an early symptom of hemorrhoidal disease, and other diagnoses, most commonly anal fissure, should be sought and excluded.

Examination. Because many benign and malignant pathologic conditions are initially misdiagnosed as hemorrhoids, a thorough examination is critical for accurate diagnosis (Table 70.2). Although the examination can be performed in prone jackknife position, the left lateral or Sims position is usually less stressful and embarrassing to patients. The physician's discretion, sensitivity, and communication with the patient, for example warning the patient of pressure to the perineum or anus, makes effective examination more likely.

Anal skin tags, an external fistula opening, perianal excoriation from anal discharge, and anal fissure can be easily detected.

TABLE 70.2**THE COMPLETE DIGITAL RECTAL EXAMINATION****PREPARATION**

Enema
 Left lateral decubitus position
 Lighting, gloves, lubrication, anoscope

VISUALIZATION

Distract the buttocks
 Inspect for:
 Soiling
 Excoriation or abrasion
 Scarring
 Patulous anus, deformity or flattening of folds
 Fissure
 External fistula opening
 Anal wink reflex
 Prolapse through anus with strain
 External hemorrhoids

PALPATION

Slow insertion of gloved, lubricated finger
 Pain with exam
 Palpable sphincter defect
 Perineal body scarring
 Anal stenosis
 Relaxed or increased tone
 Prostate abnormalities (men) or anterior rectocele (women)
 Gross blood present
 Muscle function: squeeze
 Adequate
 Accessory muscle use
 Strain
 Adequate
 Puborectalis relaxation
 Prolapsing tissue
 Other organ prolapsed

The most accurate method of diagnosis for prolapsing hemorrhoids is to observe the patient straining on a commode.

Internal hemorrhoids are soft and usually cannot be palpated. Digital examination may detect anal stenosis or an anal scar. The anal sphincter tone and sphincter squeeze can be subjectively evaluated. A mass in the anal canal can be detected, and, in male patients, the prostate can and should be carefully examined.

After visual inspection and digital examination, anoscopy can be performed. Anoscopy should not be done in patients with acutely painful conditions such as fissure or perianal abscess; it can be deferred until the painful pathology has resolved. Inserting the anoscope reduces any hemorrhoidal prolapse, so anoscopy in a patient with symptomatic hemorrhoids typically shows only mucosal redundancy above the dentate line. Anoscopy may detect other lesions such as warts or a hypertrophic anal papilla.

Proctoscopy or flexible sigmoidoscopy should be used in all cases in which bleeding is present, to rule out polyps, carcinoma, and inflammatory bowel disease, which can have symptoms identical to hemorrhoidal complaints. Even in young patients, and even if the rectal bleeding is 'obviously' from hemorrhoids, a sigmoidoscopy has minimal risk and is a key compo-

**FIGURE 70.13.** Rubber band ligation of an internal hemorrhoid.

nent of complete examination. In patients 50 years of age and older, or in patients with a family history of colorectal cancer, a complete colonoscopy should be performed.

Treatment. Prolapse of anal cushions may be initiated by the shearing effect of the passage of hard stool, by excessive downward pressure as with constipation, pregnancy, or childbirth, or by precipitous defecation as in urgent diarrhea. Reducing straining may eliminate prolapse and ameliorate symptoms, thus the rationale of adding fiber to the diet, which produces soft, bulky stool. A high-fiber diet with fiber supplements is ideal for first- and second-degree hemorrhoids, and it is an important adjunct to surgical treatment.

3 Rubber Band Ligation. Rubber band ligation is suitable for symptomatic first-, second-, and some third-degree internal hemorrhoids that do not respond to fiber supplementation. The procedure is performed in the office through an anoscope, and bowel preparation is not needed. The band should be placed on the upper anal canal or distal rectal mucosa, after pinching to test for somatic sensation (Fig. 70.13). Ligation of up to three hemorrhoids at one setting has good results, and additional ligation can be performed 4 to 6 weeks later.

Rubber band ligation may be painless, but some patients may experience discomfort, aching, or an uncomfortable sense of rectal fullness. Warm sitz baths may help, and an appropriate analgesic should be prescribed. Immediate severe or progressive pain indicates a misplaced band too close to the dentate line and requires immediate removal of the rubber band with a pointed (no. 11) blade or band cutter. Delayed anal pain, urinary retention, and fever suggest infection, which while very rare can be life threatening. Prompt and aggressive treatment includes antibiotics and examination in the operating room, with drainage and débridement as necessary. A large retrospective review indicated a cumulative success rate of 80% for symptomatic relief of all grades of internal hemorrhoids, with a 30% recurrence rate after the first banding episode. Postbanding complication rates were 2.8% for bleeding, 1.5% for thrombosis, and 0.09% for bacteremia.⁹

Sclerotherapy. Sclerotherapy with various substances (phenol, olive oil, sodium tetradecyl sulfate) can be performed in the office setting for first- or second-degree hemorrhoids in conjunction with banding, or for bleeding hemorrhoids that are

too small to band. Using an anoscope, a narrow-gauge needle is used to inject 1 to 2 mL of sclerosant in the submucosal space just proximal to the hemorrhoidal bundle.

Infrared Photocoagulation and Electrosurgery. Infrared photo-coagulation coagulates tissue protein or evaporates water in the cells, depending on the intensity and duration of application. As in sclerotherapy, an infrared probe is applied just proximal to the internal hemorrhoids through an anoscope. Infrared photo-coagulation results for first- and second-degree hemorrhoids are comparable with those of rubber band ligation. Pain and complications are infrequent. An electrocautery unit works as well.

- 4 Hemorrhoidectomy.** Hemorrhoidectomy should be considered when the hemorrhoids are mixed internal and external, are severely prolapsed through the anus, or are complicated by associated pathology, such as ulceration, fissures, fistulas, large hypertrophied anal papillae, or extensive skin tags. In many cases, hemorrhoidectomy can be performed using local anesthesia with monitored sedation. In obese individuals, general or spinal anesthesia may be easier. The patient is placed in the prone jackknife position with buttocks taped apart for visualization. An elliptical excision starts at the anoderm, includes external and internal hemorrhoidal components, and ends at the anorectal ring. One to three quadrants are most typically addressed, starting with the largest. It is important to spare all possible anoderm to avoid anal stricture. The mucosa and submucosa are dissected off of the underlying internal sphincter muscle (Fig. 70.14). Excessive bleeding indicates that the hemorrhoidal plexus is being violated, suggesting the dissection is too superficial. Alternatively, excising too deeply damages the internal sphincter fibers. Unless there is an associated anal stenosis or chronic anal fissure, internal sphincterotomy is never performed. The entire wound is closed with running absorbable suture and dressed with ointment, a fluff dressing to the perineum, and mesh shorts.

Urinary retention is a common complication of hemorrhoidectomy, and it can be minimized by restricting intravenous fluids during and after the procedure. Warm sitz baths can be started the next morning, and patients may use a gentle laxative as necessary.

Stapled Anopexy. The Longo stapled anopexy, known as PPH (Procedure for Prolapse and Hemorrhoids) is a significant innovation in the treatment for prolapsing internal hemorrhoids. Instead of removing columns of hemorrhoidal tissue, this operation removes a sleeve of the distalmost rectal mucosa and submucosa, elevating the anal canal and fixing it in place (hence *anopexy*) and radically reducing the redundancy of the mucosa. The conceptual advantage is that the incision is all proximal to the dentate line, so it should hurt much less than a standard hemorrhoidectomy. The PPH procedure is done by placing a purse-string suture in the submucosa 4 to 5 cm proximal to the dentate line (Fig. 70.15). The purse string is tightened as the specially designed circular stapler is inserted into the rectum. After the anvil passes proximal to the purse string, the suture ends are pulled through channels in the stapler to use as stay sutures and manipulate the redundant rectal mucosa. The stapler is closed and fired, and pressure is held to aid in hemostasis. In female patients, one must ascertain before firing that no vaginal tissue is caught in the staple line. After stapler withdrawal, additional sutures are often required to assist with hemostasis.

A randomized trial comparing the PPH procedure with rubber band ligation found significantly increased pain and morbidity using the stapler but significantly increased recurrent bleeding with banding.¹⁰ A systematic review of 15 randomized trials of stapled anopexy compared to excisional hemorrhoidectomy demonstrated significantly shorter operative time (weighted mean difference, -13 minutes), return to work (-4 days), and significantly decreased pain.¹¹ At 6 months postoperatively, odds of recurrent symptoms using

FIGURE 70.14. Technique of internal closed hemorrhoidectomy. **A:** Exposure of hemorrhoid with elliptic excision starting at perianal skin and extending to anorectal ring. **B:** Submucosal hemorrhoidal plexus dissected from the internal sphincter, anoderm, and mucosa. **C:** Wound closed with a running suture.

this technique were calculated at 3.64 compared with conventional excision. A report of 1-year follow-up from a randomized trial of the stapled technique versus conventional hemorrhoidectomy reported similar significant short-term benefits.¹²

Management of Special Hemorrhoid Situations

Thrombosed External Hemorrhoids. Thrombosis is a fairly common complication of hemorrhoidal disease, often appearing as an independent problem, apparently unrelated to internal hemorrhoids. The reason for the acute thrombosis is usually unknown. There is an abrupt onset of anal mass and pain that peaks within 48 hours. Usually, the pain then recedes, leaving a subcutaneous lump. Sometimes the skin overlying the clot becomes necrotic, leading to bleeding and eventual extrusion of the clot. Treatment is aimed at relief of pain, prevention of recurrent thrombosis, and (though this is of secondary importance) prevention of residual skin tags. If the patient presents with severe pain, the thrombosis should be excised in the office or emergency room. This can usually be done under local anesthesia, and the wound is left open without packing. The pain of

FIGURE 70.15. Stapled circular hemorrhoidectomy or procedure for prolapsing hemorrhoids. **A:** A purse-string suture is placed in the rectal mucosa proximal to hemorrhoids. **B:** The stapler anvil is placed proximal to the purse string, and the purse string is tied down to draw hemorrhoidal tissue into the staple line. **C:** The stapler is fired and removed, excising a sleeve of distal rectal tissue and creating a stapled anastomosis.

incision is usually eclipsed by the relief of pain from the thrombosis, so patients often experience dramatic relief. However, if the pain is already subsiding and the clot resolving, patients may be managed expectantly with warm sitz baths for comfort and fiber supplementation to bulk and soften stool. Patients must be warned of a relatively high recurrence rate of acute thrombosis: 6% after excision and 25% after expectant treatment.¹³

Incarcerated Hemorrhoids. Incarceration indicates irreducibly prolapsed, fourth-degree hemorrhoids. This is the one situation in which internal hemorrhoids cause pain. The diagnosis is

obvious on examination: edematous internal hemorrhoids protrude from the anus, usually with large external components as well. Pain is usually severe and urinary retention is common. Untreated, incarceration may progress to strangulation with mucosal necrosis. Treatment is urgent or emergency hemorrhoidectomy. As in other hemorrhoid procedures, antibiotics are not indicated.

Hemorrhoids in Pregnancy and Postpartum. Hemorrhoids can occur as the result of downward pressure from a gravid uterus or from prolonged labor and may be exacerbated by hormonal changes. For thrombosed external hemorrhoids, symptomatic internal hemorrhoids, or incarcerated hemorrhoids, standard treatment can be performed safely and should not be withheld. Left lateral decubitus position is usually recommended in the third trimester.

Bleeding Rectal Varices from Portal Hypertension. The incidence of hemorrhoidal disease of the anus in portal hypertension is no greater than in the normal population. Although uncommon, bleeding from rectal varices in patients with portal hypertension can be life threatening and may initially simulate hemorrhoidal bleeding. Transanal suture of the bleeding vessel should incorporate mucosa, submucosa, and muscular wall of the rectum. This should be done in the operating room, ideally after correcting any coagulopathy. Rubber band ligation and hemorrhoidectomy should not be done on the bleeding portal hypertensive patient, because they create more bleeding opportunities and do not address the source of bleeding. Local control of rectal and anal varices may be achieved by using the PPH anopexy as a devascularization procedure,¹⁴ but definitive control of varices requires reduction of elevated portal pressures by transjugular intrahepatic portosystemic shunting (TIPS) or liver transplantation.

Hemorrhoids in Inflammatory Bowel Disease. Hemorrhoidal problems in inflammatory bowel disease are uncommon. Most anal problems are either inflammatory (anal fistula, atypical fissure, etc.) or the result of diarrhea causing perianal irritation, rather than the result of hemorrhoids themselves. Treating the primary disease symptomatically usually suffices to control secondary anal symptoms. Rubber band ligation, hemorrhoidectomy, and stapled anopexy should almost never be done on the inflammatory bowel disease patient.

Rectal Prolapse

- 5** Rectal prolapse (procidentia) is an uncommon condition in which the rectum intussuscepts into itself and prolapses through the anal canal. Although the diagnosis is usually obvious, one may have to distinguish early rectal prolapse from severely prolapsed hemorrhoids. Full-thickness rectal prolapse displays concentric circular folds, whereas mucosal prolapse displays radially oriented folds. Rectal prolapse has a female-to-male ratio of at least 5:1. Perhaps associated with dysfunctional bowel habits or with constipating psychotropic medications, rectal prolapse is seen disproportionately among patients with dementia, mental retardation, and schizophrenia.

Pathophysiology. The cause of rectal intussusception and prolapse is not understood. Intussusception usually starts in the anterior rectum. Many patients with rectal prolapse have a history of constipation and straining or, less commonly, chronic diarrhea. Studies of anorectal function and defecation dynamics reveal that these patients have impaired resting and voluntary sphincter activity, decreased functional rectal capacity, impaired continence, and puborectalis dyssynergy (inappropriate contraction) during defecation. Loss of continence is caused by reduced sphincter tone due to mechanical stretching

TABLE 70.3 ETIOLOGY**ANATOMIC DEFECTS OR ABNORMALITIES IN PATIENTS WITH CHRONIC RECTAL PROLAPSE**

- Abnormally deep rectovaginal or rectovesical pouch
- Lax and atonic musculature of the pelvic floor
- Lack of normal fixation of the rectum and an elongated mesorectum
- Unusually redundant sigmoid colon
- Lax and atonic anal sphincter

by the prolapsed bowel, traction injury to the pudendal nerves, and loss of normal sensation.

Anatomic Abnormalities. Several anatomic defects or abnormalities are consistently demonstrated in patients with chronic rectal prolapse (Table 70.3). These defects are seen concurrently with long-standing prolapse, making the distinction between cause and effect difficult.

Solitary rectal ulcer syndrome is a vexing condition associated with occult or overt prolapse, in which there is bleeding, tenesmus, and an anterior rectal ulcer that may appear proliferative, like a polyp or cancer.

Evaluation. Physical examination reveals a patulous anus with decreased sphincter tone. When the prolapse itself is not obvious, it is best demonstrated by asking the patient to strain while seated on a commode. Anoscopy or rigid proctoscopy may demonstrate associated conditions, such as anterior rectal erythema or ulceration. Anal manometry documents baseline function preoperatively but does not help predict the outcome of surgery. Cinedefecography confirms the diagnosis of intussusception when in doubt (Fig. 70.16) and it can detect other anatomic and functional abnormalities such as nonrelaxing puborectalis muscle or enterocele. Colonoscopy is indicated to evaluate bleeding and to rule out a cancer or polyp as the lead point for intussusception, a rare but not unheard of condition.

Treatment. Acute prolapse should be reduced with steady manual pressure to prevent incarceration and strangulation. Reduction of an edematous, incarcerated prolapse can be facilitated by application of granulated table sugar. Operations generally suspend or remove the intussuscepting rectum. Methods of repair are abdominal and perineal, the former represented by rectopexy (open or laparoscopic, with or without a concomitant sigmoid resection) and the latter represented by the Altemeier perineal proctectomy and Delorme plication. Abdominal operations generally have recurrence rates less than 10% and are used in fit patients. Transperineal operations have recurrence rates of 15% to 20% (or more in some series) and are most appropriate in patients at high risk for

complications of abdominal surgery. Perineal operations are often recommended to young men in an effort to avoid sexual dysfunction following a pelvic dissection, but few comparative data are available. Female sexual function is poorly described following either abdominal or perineal repairs.

Transabdominal rectopexy involves a full mobilization of the rectum to the level of the pelvic floor musculature with suture fixation of the mesorectum to the presacral fascia below the sacral promontory (Fig. 70.17). The recurrence rate has been reported to be 6% to 9% with up to 10-year follow-up.¹⁵ Suture rectopexy is associated with symptomatic constipation in about 50% of cases.¹⁶ About 50% of rectal prolapse patients with fecal incontinence improve after prolapse repair. Because return of continence may take 6 to 12 months, any operation to treat incontinence should be deferred for a year after a successful prolapse repair.

A multicenter cohort study of abdominal approaches to prolapse repair found pooled 5- and 10-year recurrence rates of 7% and 29%, respectively. No recurrence difference was identified based on performance of mobilization, resection, or rectopexy; that is, mobilization-only had the same recurrence rate as mobilization-resection-rectopexy, nor was there a difference in recurrence between suture and mesh rectopexy or between laparoscopic and open approaches.¹⁷ These findings support the notion that prolapse is probably alleviated by formation of presacral adhesions during the postoperative period.

Perineal rectosigmoidectomy (Altemeier operation) is a transanal approach in which the prolapsed rectum and redundant sigmoid colon are excised endorectally, analogous to vaginal hysterectomy. The operation is performed with the patient in the lithotomy (Fig. 70.18) or prone jackknife position. Patients tolerate this operation well, with minimal postoperative pain. A levatorplasty (anterior, posterior, or both) can be performed via the same incision and may help recreate the anorectal angle. Several series report a recurrence rate of about 16% with a relatively short-term follow-up.¹⁸ Major long-term complications include recurrence, fecal urgency due to the smaller sigmoid reservoir after rectal excision, tenesmus, and anastomotic stricture—in other words, the complications of any anterior rectal resection.

The Delorme procedure is another transperineal approach. This is used for rectal near-prolapse (internal intussusception) or for overt prolapse. With the patient in the prone position, the redundant submucosa is stripped circumferentially using electrocautery, continuing proximally until it is taut. The submucosal tube is then transected and the proximal end anastomosed to the dentate line. The denuded rectal wall is incorporated into the suture line with reefing bites to eliminate dead space (Fig. 70.19). Like perineal rectosigmoidectomy, this procedure causes little pain, but it has a high recurrence rate.

A reasonable approach to the problem of rectal prolapse is to use a perineal operation for older, sicker patients and an abdominal approach for younger, healthier ones. The uncertain

FIGURE 70.17. Transabdominal rectopexy. After full mobilization of the rectum, the endorectal fascia and peritoneum on each side is sutured to presacral fascia, below the promontory of the sacrum.

nature of functional results (constipation, incontinence) should be shared with patients in preoperative discussion.

Anal Incontinence

Definition and Etiology. *Anal incontinence* describes a spectrum of functional impairment that ranges from involuntary passage of flatus to involuntary passage of formed stool. Almost any loss or disturbance of normal anatomy or function—postresection loss of reservoir function, rectal inflammation, and so on—may result in anal incontinence. Disturbance of anorectal sensation may prevent awareness of stool and lead to leakage. A bolus of diarrheal stool emptying rapidly into the rectum may overcome anal continence, even in healthy people. Common mechanical injuries to the sphincters include obstetric tear, fistulotomy, internal sphincterotomy, and trauma. Age and female sex are the two major risk factors for incontinence; these have an important but poorly understood interaction.

Incontinence may not manifest for two or more decades after obstetric injury.

Evaluation. The previously outlined physical examination (Table 70.2) can help to differentiate the presence of a neurologic or muscular problem. For example, a patulous or lax anus may indicate neurogenic dysfunction of the sphincter muscles. A scar or defect in the anal region may indicate old surgical injury, and a thin perineal body suggests an obstetric sphincter injury.

In addition to history and physical examination, several anatomic and physiologic tests can be done. The most useful of these, endoanal ultrasonography, provides a circumferential anatomic image of the internal and external sphincter. Endoanal ultrasound can clarify and map sphincter defects, confirming the need for sphincteroplasty, and conversely it can reveal an intact sphincter, contraindicating sphincteroplasty. An intact but thinned portion of sphincter may be due to denervation, which is suggested by a prolonged pudendal nerve

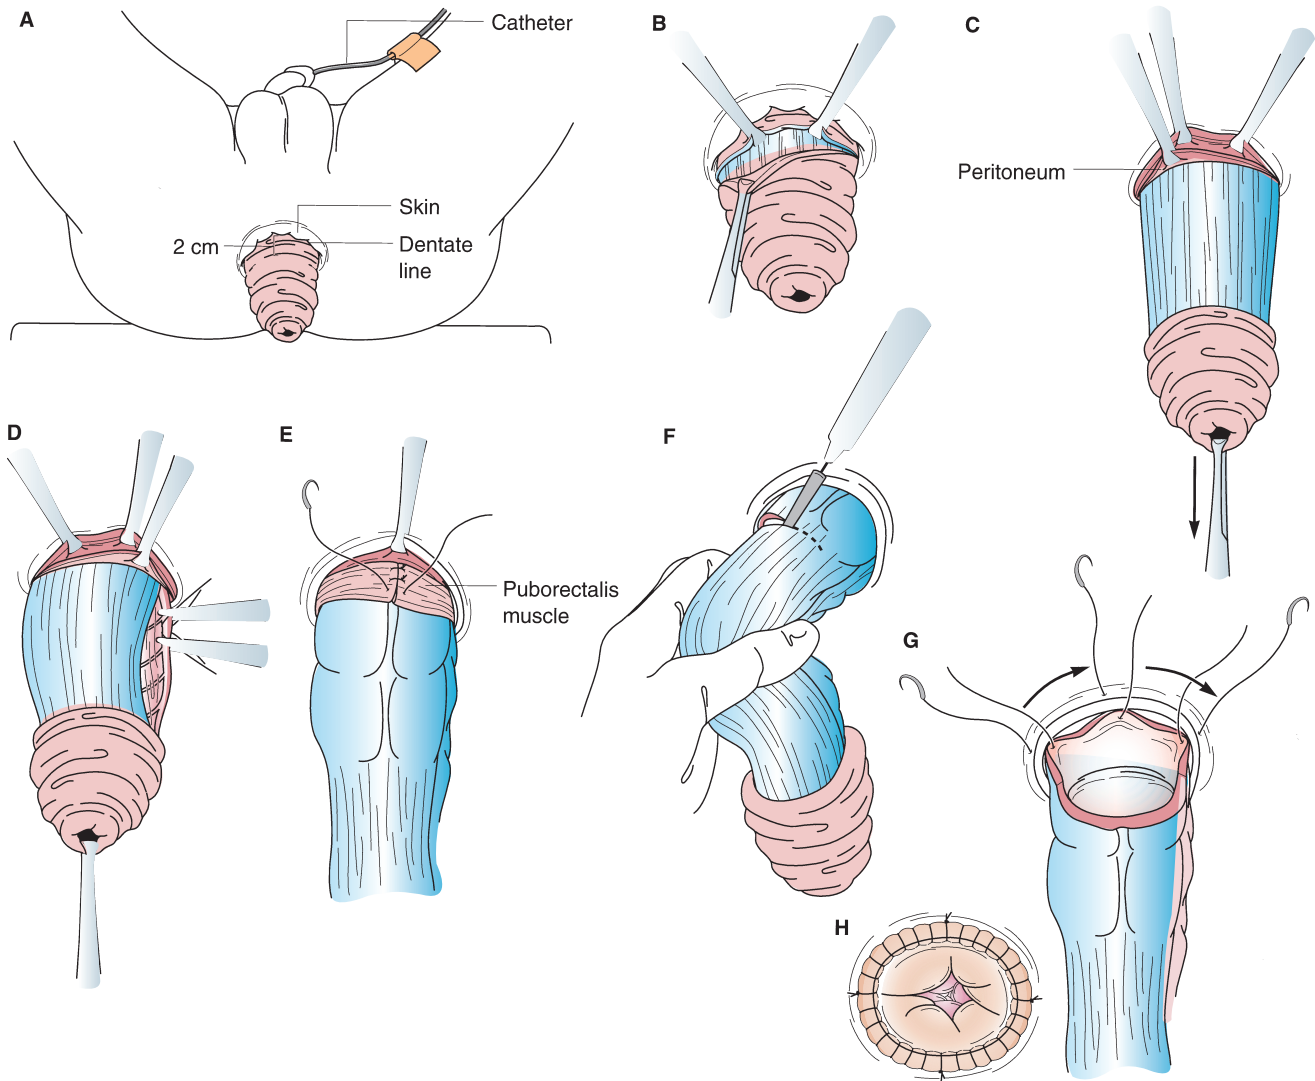

FIGURE 70.18. Perineal rectosigmoidectomy. The patient is placed in the lithotomy position with both legs in gynecologic stirrups. **A** and **B**: A circular incision is made on the prolapsed rectum 2 cm proximal to the dentate line. **C**: The peritoneal attachment is dissected from the anterior rectal wall, thus opening into the peritoneal cavity. **D**: The mesorectum or mesosigmoid is clamped and divided laterally and posteriorly. **E**: This is followed by approximation of the puborectalis. **F**: The anterior wall of the protruding rectum is cut 1 cm distal to the anal verge. **G**: Stay sutures of 3-0 synthetic absorbable material are placed in four quadrants. **H**: Anastomosis with running stitches.

terminal motor latency. Anal manometry establishes baseline resting and squeeze pressures, although results do not correlate well with operative outcomes. Defecography can aid operative planning by identifying previously unrecognized disorders such as rectocele or internal intussusception. None of these tests by itself correlates with incontinence, and fully continent control subjects may also have sphincter defects and manometric abnormalities, so treatment is still geared to the patient's symptoms.

The clinical evaluation of anal incontinence ideally includes an assessment of symptom severity and quality of life. With the same degree of objective incontinence, patients' subjective experience can be surprisingly different. For example, one patient may be housebound because of fear of minor soiling, whereas another patient may make little change in her or his daily activities despite occasional episodes of complete incontinence. Because anal incontinence is more a quality of life problem than a health risk, the patient ultimately determines the need for intervention. Although a formal, validated assessment of quality of life and symptom severity is not necessary, it can help by establishing a baseline score for later comparison.

Several validated severity and quality of life scores are available.¹⁹

Management. One of the key early steps in incontinence treatment is medical regulation of bowel habits, with the goal of decreasing bowel movements to once a day or every other day. Sometimes this simple intervention resolves chronic, difficult symptoms. A high-fiber diet and the use of fiber supplements lead to bulkier stools, which are easier to sense and to control. Antidiarrheal drugs such as loperamide, diphenoxylate, and bile acid binders make stool harder and less frequent, thus easier for the marginal or damaged sphincter to handle.

Biofeedback physical therapy can be used to regain anorectal sensation and to retrain coordinated contraction/relaxation of the pelvic floor and sphincter muscles. Biofeedback training can help up to 85% of patients with anal incontinence, though some of this effect is likely due to the associated counseling and dietary management.^{20,21} Most systems include a balloon catheter and pressure transducer. While the patient watches the manometry tracings, the balloon is inflated, and the patient is coached to contract the external sphincter muscle, elevating

FIGURE 70.19. Modified Delorme procedure. Patient is placed in the prone position. **A** and **B**: With a Pratt speculum used for exposure, a circumferential incision is made 1 cm proximal to the dentate line. The submucosa is dissected from the underlying internal sphincter. At the level of the anorectal ring, the Pratt speculum is replaced by Gelpi retractors placed at a right angle to the dentate line. **C** and **D**: Proximal to the anorectal ring, the dissection continues in the mucosal plane until the mucosa resists being pulled down. The mucosal tube is then cut. **E** and **F**: With 3-0 synthetic absorbable sutures, the mucosa at the upper cut end is brought down to the mucosa at the lower cut end, taking along the denuded anorectal wall. Eight such sutures are placed all around. **G**: At completion of the anastomosis, the anorectum is plicated.

the tracing. It may take several biofeedback sessions before the patient is aware of the sensation of a full rectum and can contract the sphincter effectively.

Operation is reserved for refractory incontinence. Sphincteroplasty is most suitable for incontinence from obstetric injury or injury after previous anorectal surgery, if there has been preoperative documentation of a sphincter defect. A curved incision is made over the sphincter disruption, parallel to the anal verge. The sphincters are mobilized laterally to allow an overlapping plication with mattress suture, and after plication the anus should still permit digitation (Fig. 70.20). Simultaneous levatorplasty can help support the repair and lengthen the anal canal, but it may contribute to postoperative dyspareunia. Overlapping sphincteroplasty yields short-term improvement in about 85% of patients, but only 40% maintain continence over a 10-year period.²² Risk of functional failure increased with patient age.

Another sphincter substitute is the artificial anal sphincter (Acticon Neosphincter, American Medical Systems, Minnetonka, MN; Fig. 70.21), the only such device approved by

the U.S. Food and Drug Administration (FDA). With a pump in the labium majus or scrotum, a retropubic reservoir, and an inflatable silicone cuff around the upper anal canal, the artificial sphincter can provide satisfactory continence for many patients who have failed or are not amenable to more conventional therapy^{23,24} Reoperation is required in about half of patients, primarily because of infection, and this usually necessitates removal of the device. Cuff implantation can be technically difficult due to the common history of multiple previous operations, and success rates are best in the hands of surgeons who are highly experienced with the technique.

Sacral nerve stimulation (SNS) is a novel intervention for anal incontinence that has the advantage of avoiding surgery in the anal region altogether. A quadripolar lead is implanted using a percutaneous technique, most commonly in one of the S3 foramina. The procedure is usually performed under monitored local anesthesia. The patient undergoes a period of test stimulation to assess the effect of stimulation; if continence is significantly improved, a pulse generator is implanted in the buttock at a second operation. The exact mechanism of action

FIGURE 70.20. Overlapping anal sphincteroplasty.

FIGURE 70.21. Implanted silicone neosphincter. A: Female. B: Male.

for SNS is uncertain. Impressive results have been reported for incontinent patients with and without sphincter defects, and associated morbidity is low.²⁵ However, at the time of this writing, the FDA has not yet approved SNS for treatment of anal incontinence in the United States.

For patients with refractory and incapacitating anal incontinence, a permanent end-sigmoid colostomy remains a relatively simple and low-risk solution that is generally associated with high patient satisfaction and an improved quality of life.

Anal Fissure

6 Definition. Anal fissure is an ulcer in the lower anal canal. Fissures are acute or chronic, primary or secondary. A primary fissure arises without association to other local or systemic disease, whereas a secondary fissure may be due to Crohn disease or ulcerative colitis. Atypical anal ulcers, especially those off the midline, may be due to HIV, anal cancer, tuberculosis, syphilis, or hematologic malignancy.

Pathophysiology. Studies show that resting anal pressure (internal sphincter tone) in patients with anal fissure is significantly higher than normal, whereas squeeze pressure (external sphincter contraction) is normal. Doppler flowmetry has shown anal canal perfusion to be poorest posteriorly, with reduced anodermal blood flow at fissure sites, suggesting that chronic nonhealing fissures are caused and maintained by ischemia. Reduction of anal pressure by sphincterotomy improves anodermal blood flow, resulting in fissure healing.²⁶

Clinical Manifestations. Anal pain, particularly during and after bowel movement, is the most prominent symptom, followed by bleeding with defecation. Anal fissure pain can be severe and incapacitating. Constipation is a common association, both as a precipitating event and as a result of deferring painful defecation.

Diagnosis. Although pain and bleeding are typical of anal fissure, the diagnosis is confirmed by examination. When performed gently, inspection by spreading the buttocks will reveal the fissure in most cases. In general, digital and anoscopic examinations are deferred when a fissure is diagnosed because they are too painful. In men, almost all fissures are located in the posterior midline, whereas 10% of fissures in women are in the anterior midline. The *sentinel pile*, a protruding tag at the distal end of the fissure, is often the presenting complaint (a 'painful hemorrhoid'), and patients with anal fissures frequently have an associated hypertrophic anal papilla at the dentate line.

Management. Initial treatment of acute anal fissure is pain relief, with warm sitz baths to relax the anal canal. Application of topical anesthetic gel or ointment directly to the fissure before bowel movement is sometimes helpful. Bulking and softening the stool with fiber supplementation and increased water intake (8–10 glasses/day) is the mainstay of therapy. Acute anal fissures should heal within 6 weeks.

For chronic anal fissure, a reasonable first treatment is the application of 0.2% nitroglycerine or 2% diltiazem ointment directly to the fissure. Both medications reduce anal resting pressure and increase anodermal blood flow. Patients should be warned of possible associated headaches with nitroglycerine; the standard commercially available nitroglycerine ointment is 2%, too strong for topical perianal use, so it must be diluted. Fissure resolution after 6 weeks of topical treatment has been reported at 50% to 75%, but up to half of these will recur. Botulinum toxin A injection into the internal sphincter is another approach to reduce internal anal sphincter hypertonicity,

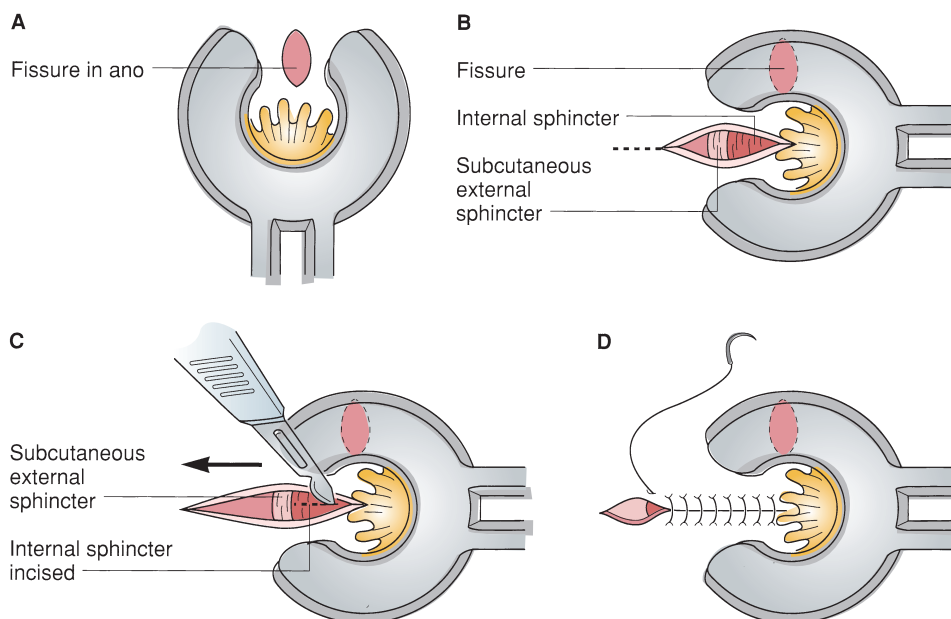

FIGURE 70.22. Lateral internal sphincterotomy (closed technique). **A:** Triad of fissure, sentinel pile, and hypertrophied anal papilla. With an anal speculum used for exposure of the lateral quadrant, a no. 11 scalpel blade stabs into the subcutaneous tissue from the anal verge to the dentate line, with the knife in the horizontal position. **B:** The knife is turned 90 degrees, and the internal sphincter muscle is cut while the anal canal is stretched open.

although technique, dose, and success rates have varied significantly. A cohort study of patients treated with botulinum toxin for fissure demonstrated 42% recurrence at a median of 42 months.²⁷ Potential ill effects of botulinum injection include transitory incontinence (up to 3 months), hematoma, thrombosis, and infection.

Lateral internal sphincterotomy, under local, spinal, or general anesthesia, is the next step for the unhealed chronic anal fissure refractory to medical therapy (Fig. 70.22).²⁸ Lateral internal sphincterotomy is also indicated in patients whose pain is too severe to tolerate a trial of medical therapy. This is an outpatient procedure that can be performed under local, regional, or general anesthesia. In the closed method of sphincterotomy, a

speculum is opened gradually wider, stretching the internal sphincter, which then feels like a bowstring. This muscle is then cut with a small knife passed through the skin, so there is only a stab incision (Fig. 70.23). The midline fissure is left undisturbed, but the sentinel pile, redundant skin, or the hypertrophied anal papilla can be excised if it is bothersome. Open technique uses a longer incision for the same operation. A cohort study of 35 patients who had failed nonoperative management reported 94% fissure healing after open sphincterotomy.²⁹ However, a few patients may experience minor alterations in continence following sphincterotomy.³⁰ A Cochrane review indicated that sphincter stretching and posterior sphincterotomy are less effective and more likely to cause incontinence.³¹

FIGURE 70.23. Lateral internal sphincterotomy (open method). **A:** The fissure in the midline is left alone. **B:** With a speculum used to expose the left lateral quadrant, an incision is made through the subcutaneous tissue to expose both the subcutaneous external sphincter and the internal sphincter. **C:** The internal sphincter is incised to its full thickness; care is taken not to cut the external sphincter. **D:** The wound is closed.

Secondary Anal Fissure. Fissures or ulcers that develop as a result of underlying disease tend to be larger and deeper than primary fissures, and they are less likely located in the posterior midline. Pain is rarely as severe as the pain of primary fissure, and muscle-relaxing therapies (topical medications and sphincterotomy) do not help. A nonmidline or otherwise atypical fissure should be biopsied.

Neutropenic fissures occur in patients with leukemia, aplastic anemia, agranulocytosis, and similar diseases. The fissure may follow a bout of diarrhea or constipation at a time when the patient is neutropenic. This type of fissure is often very painful and may have a necrotic base. Treatment is symptomatic only, and the ulcer should heal when neutropenia resolves.

ANORECTAL ABSCESES

Pathogenesis

- 7 In the wall of the anal canal, four to ten anal glands open directly into the anal crypts at the dentate line. Infection of the anal glands, presumably incited by a blocked duct or orifice, is the origin of perianal abscesses. Because the anal glands lie between the internal and external sphincter muscles, an intersphincteric abscess forms first. The infection may then spread to the spaces discussed previously (Fig. 70.24). Abscess locations, in order of frequency, are perianal, ischioanal, intersphincteric, and supralelevator.

Clinical Manifestations

The initial symptom of most anorectal abscesses is severe anal pain, aggravated by activity. Swelling is usually prominent, and skin changes become obvious as the abscess nears the surface. Some patients develop urinary retention.

Management

Like all abscesses, the anorectal abscess must be drained as soon as possible. Antibiotics do not help and should be avoided, except in immunosuppressed or immune-deficient patients, in whom antibiotics should be considered. Packing is generally discouraged as painful and impractical.

Perianal abscesses are the most superficial and the easiest to treat. They are usually small and can be drained under local anesthesia. An elliptical or cruciate incision is made on the

most prominent part of the skin and subcutaneous tissue overlying the abscess cavity. Redundant skin edges are excised to prevent premature closure of the abscess. No packing should be necessary.

An ischioanal abscess causes a diffuse swelling of the ischioanal fossa, and drainage can be done wherever the abscess is most superficial. Bilateral ischioanal or horseshoe abscess has its origin in the deep postanal space, with spread to both ischioanal spaces. A horseshoe abscess should be drained through the deep postanal space, avoiding division of muscle. A longitudinal incision is made in the skin between the tip of the coccyx and the anus to expose the anococcygeal ligament. The anococcygeal ligament is incised along its fibers, and the deep postanal space is entered. After the abscess cavity is drained and irrigated, a counterincision is made on one or both limbs of the ischioanal space.

Unlike perianal and ischioanal abscesses, there is no external swelling or induration in the perianal area in intersphincteric abscesses. The diagnosis is suspected when there is severe anorectal pain and no evident pathology. Focal tenderness is present when careful, systematic circumanal palpation is performed. Most intersphincteric abscesses are located posteriorly. Intersphincteric abscesses are drained through the anal canal by incising the mucosa and cutting through the internal sphincter muscle.

Supralelevator abscess is uncommon and difficult to diagnose. Because it is adjacent to the abdominal cavity, a supralelevator abscess can mimic an acute abdomen. Digital examination reveals an indurated or bulging tender mass on either side of the lower rectum or posteriorly above the level of the anorectal ring. The supralelevator abscess may arise by extension of an intersphincteric abscess, by extension of an ischioanal abscess, or from intra-abdominal processes such as diverticular, appendiceal, and Crohn disease abscesses. If the abscess is from upward extension of an intersphincteric abscess, it should be drained into the rectum. If such an abscess is drained through the ischioanal fossa, a complicated suprasphincteric fistula can be formed. If the supralelevator abscess arises from the upward extension of an ischioanal abscess, it should be drained through the ischioanal fossa.

ANAL FISTULA

- 8 Anal fistula (fistula in ano) results when an anorectal abscess that is spontaneously or surgically drained does not heal completely, becoming instead an inflammatory tract with an internal opening in the anal crypt at the dentate line and an external opening on the skin. Every abscess becomes a fistula the

FIGURE 70.24. Pathways of infection start in the intersphincteric space (A) and then spread to perianal spaces, forming perianal abscesses (B).

FIGURE 70.25. The four main anatomic types of fistula.

moment it is drained, because of the addition of an external opening, but about half of these fistulas disappear over a 2-month period. If the external opening (incision and drainage site) is still open after 60 days, one may assume it is a chronic anal fistula and will never heal without an operation.

Classification

The four subtypes of anal fistula are named for the relation of the fistula to the sphincter muscles (Fig. 70.25).³²

Intersphincteric Fistula (most common). The fistulous tract is in the intersphincteric plane. The external opening is in the perianal skin, close to the anal verge. A drained perianal abscess is an intersphincteric fistula.

Transsphincteric Fistula (fairly common). The fistulous tract starts in the intersphincteric plane, then traverses the external sphincter, with the external opening over the ischioanal fossa. Horseshoe fistulas are also in this category. A drained ischioanal abscess is a transsphincteric fistula.

Suprasphincteric Fistula (rare). The fistula typically starts in the intersphincteric plane and then passes upward to a point above the puborectalis muscle. The tract passes laterally over this muscle and downward between the puborectalis muscle and the levator ani, into the ischioanal fossa.

Extrasphincteric Fistula (rare). The fistula passes from rectal wall (not the anal canal) through the levator ani and the ischioanal fossa. Extrasphincteric fistulas may arise from trauma, a foreign body, or a pelvic abscess, such as diverticular or appendiceal abscess.

Clinical Manifestations

Most fistula patients have a previous history of anorectal abscess, followed by intermittent spontaneous or surgical drainage. Recurrence of a perianal abscess indicates an anal fistula. The external opening is usually visible as a red elevation of granulation tissue with purulent or serosanguinous drainage on compression. In the intersphincteric fistula, the tract can be palpated as an indurated cord. Deeper fistulas usually are not palpable.

Anoscopy is done in the operating room to identify the internal opening. Proctoscopy or flexible sigmoidoscopy is usually performed to rule out other lesions and inflammatory

bowel disease. A fistula probe can be introduced into the fistulous tract to determine its direction, although it is not always possible to pass the probe through the internal opening. Occasionally the internal fistula opening or fistula pathway may be hard to discern based on physical examination. Injection of the external opening with hydrogen peroxide while performing endoanal ultrasound can demonstrate the tract, effectively creating a fistula map, and can also help to identify an unrecognized internal opening at the time of surgery. Buchanan et al.³³ studied a cohort of 108 patients with recurrent fistulae using digital examination, endoanal ultrasound, and MRI on each patient. Digital examination correctly identified 61% of tracks, compared with 81% of tracks by endoanal ultrasound and 90% by MRI.

Several disorders must be considered in the differential diagnosis of anal fistula. A pilonidal sinus with perianal extension is the closest mimic of anal fistula, although at operation it is obvious that the tract goes the wrong way, away from the anus instead of toward it. Hidradenitis suppurativa usually displays multiple perianal skin openings with surrounding leather-like skin. Infected perianal cysts are multiple and superficial, without a palpable tract. Inflammatory bowel disease fistulas are often in some way atypical, with multiple tracts or unusually superficial or deep tracts. Low rectal and anal canal carcinomas may rarely present as a fistula in the perineum. So as not to miss inflammatory bowel disease and cancers, fistula patients should be considered for flexible endoscopy.

Management

The principles of fistula surgery include unroofing the fistula, eliminating the internal opening, and establishing adequate drainage. Failure to open the entire tract generally leads to recurrence. In most fistulas, the treatment of choice involves opening the entire fistulous tract over a fistula probe. Granulation tissue is curetted out, and the edges of the wound can be marsupialized to facilitate healing. Fistulectomy, the excision of the fistulous tract, has no advantage over fistulotomy, the laying open of the tract. For horseshoe fistula, radical unroofing would result in a large wound and is not necessary. Incision of the deep postanal space combined with counterincision and curettage of the lateral tracts is generally recommended.

Any sphincter muscle division carries with it a risk of impaired continence. Individuals at particular risk include those with compromised continence to begin with, previous sphincter injury, and underlying diarrheal states such as ulcerative colitis or Crohn disease. High fistulas, those involving large amounts of external anal sphincter, are not suitable for treatment by fistulotomy due to the risk of incontinence. The anterior sphincter in women is short, and anterior fistulotomy in women is considered to be particularly risky. When the fistula tract crosses significant external sphincter, a staged procedure with the use of a seton, or encircling cord that stents the fistula open, is an ancient and successful treatment, albeit awkward and time-consuming.

The seton is drawn through the fistula tract and kept loose around the external sphincter to allow drainage of infection; this arrangement is called a draining seton. Use of a cutting seton, in which the seton is tightened over a period of weeks to cut through the sphincter and create fibrosis, risks incontinence and is not recommended.

At the second-stage operation (6 weeks to 3 months after the first), the seton is removed and some type of tract-ablating procedure may be performed. Secondary fistulotomy, once popular, runs the risk of postoperative incontinence. Fibrin glue application to obliterate the tract has the distinct advantage of cutting no muscle, but most report a long-term success rate well under 50%. Fibrin glue can be reapplied and has shown a small success rate among patients with complex fistulae among whom fistulotomy would likely result in incontinence.³⁴

The goal of fibrin glue is the formation of a collagen matrix for eventual healing, and that goal is reached more directly by the new biologic fistula plugs made of porcine or bovine collagen. This plug is drawn through the fistula tract and sutured in place. Reported success rates to date have been highly variable.³⁵

Endoanal advancement flap is another interventional option for patients who fail less invasive therapy. A U-shaped flap of mucosa and circular muscle is created, encompassing the internal opening near the distal edge. The flap is advanced, and the distal strip with the internal opening is excised. The internal opening is closed with absorbable sutures, and the flap is affixed with sutures to cover this repair.

Anal Fistula Associated with Crohn Disease

Fistulas associated with Crohn disease are often asymptomatic. They may resemble ordinary, cryptoglandular fistulas in that there is an indurated external opening in the skin that exudes pus, and a palpable tract passing toward the anal canal. On the other hand, these fistulas may be complex with multiple tracts, and they may disobey any rule laid down for the expected anatomy of typical fistulas.

The most important part of treatment is adequate and aggressive medical therapy, including medications for active Crohn disease. Metronidazole and ciprofloxacin have been found to be useful in some patients, probably for their anti-inflammatory rather than their antibiotic properties. Methotrexate and azathioprine have had minimal success. Infliximab, a monoclonal antibody directed against tumor necrosis factor, has shown promising efficacy for Crohn disease fistulas. In a placebo-controlled trial of patients with fistulizing Crohn disease in which 90% of patients also had perianal disease, 62% experienced at least 50% reduction in the number of draining fistulas compared with 26% of the placebo group.³⁶ Nearly half of patients treated with infliximab experienced complete closure of all fistulas with short- to mid-term follow-up.

Aggressive surgical intervention in complex Crohn disease fistulas is discouraged because of extremely poor healing among these patients. The basic principle is to drain any abscess and lay open superficial tracks. Division of any significant quantity of sphincter muscle should be avoided, as these patients are prone to development of additional fistulae and are also at increased risk for incontinence due to diarrhea from

their underlying Crohn disease. Long-term indwelling setons are often the best alternative in this patient population.

Rectovaginal Fistula

A rectovaginal fistula is a communication between the anterior wall of the anal canal or rectum and the posterior wall of the vagina. There are many possible causes (Table 70.4), but obstetric injury accounts for most. A rectovaginal fistula is referred to as low if a repair can be done from a perineal approach and high if repair can be accomplished only transabdominally (Fig. 70.26). Simple or complex classification is based on location, size, and cause (Table 70.5).

Clinical Manifestations. Symptoms of rectovaginal fistulas depend on location, size, and cause. In low or small fistulas, the most common complaint is passage of gas per vagina. In large fistulas, symptoms include vaginal discharge with fecal odor, passage of flatus and stool per vagina, and painful vaginitis.

Diagnosis. Diagnosis is made by physical examination. In low fistula, digital examination of the anal canal reveals scar and a defect in the anterior wall. Bimanual examination with one finger in the rectum and a finger of the other hand in the

FIGURE 70.26. Rectovaginal fistula classified by location. Fistulas are low when located at or just cephalad to the dentate line, high when near the cervix, and mid when located in between.

TABLE 70.5

CLASSIFICATION

CLASSIFICATION OF RECTOVAGINAL FISTULA

■ CHARACTERISTIC	■ SIMPLE	■ COMPLEX
Location	Low to midvaginal septum	High vaginal septum
Size	2.5 cm or less in diameter	2.5 cm or more in diameter
Cause	Traumatic or infectious cause	Inflammatory bowel disease, irradiation, neoplastic cause

vagina is also helpful. Anoscopy can also detect the opening in the anal canal. Middle and high fistulas require proctoscopy. If the fistula cannot be seen, a tampon is placed in the vaginal canal and 100 mL of dilute methylene blue is instilled into the anorectum. The tampon is then removed and checked for blue staining. Barium enema is usually not helpful but may be indicated in certain patients with inflammatory bowel disease or previous irradiation.

Management. Spontaneous or nonoperative healing of a rectovaginal fistula depends primarily on its cause and, to a lesser extent, on its size. About one half of small rectovaginal fistulas secondary to obstetric trauma heal spontaneously. Fistulas caused by Crohn disease or irradiation rarely heal spontaneously.

For a low, simple fistula and some mid-rectovaginal fistulas, endorectal advancement of an anorectal flap technique gives good results. The rectal flap, which consists of mucosa, submucosa, internal sphincter, and the circular muscle of the lower rectum, is outlined lateral and distal to the fistula. The flap is based at least 4 cm cephalad to the fistula, and the base should be twice the length of the flap to ensure adequate blood supply. After the flap is raised, the underlying fistula and the excess flap are excised. The cut edges of the internal sphincter and the circular muscle of the lower rectum are approximated, obliterating that portion of the fistula tract. The opening in the vagina is left open for drainage. The anorectal flap is then advanced over the repaired area and sutured (Fig. 70.27).

The results of endorectal advancement flap for treatment of simple rectovaginal fistula are good, with 83% of treated patients achieving primary healing of the fistula.³⁷ It is important to wait, usually 3 to 6 months, until the inflammation has subsided before considering a surgical repair. An alternative repair is to lay open the rectovaginal fistula, essentially converting it to a fourth-degree perineal tear. A layered closure of the anal and vaginal defect can be performed using synthetic absorbable sutures. However, this approach divides intact sphincter muscle and risks impaired continence. On the other hand, if the rectovaginal fistula is associated with incontinence resulting from injury to the external sphincter, a sphincteroplasty is also performed. In this technique, the ends of the transected muscle are identified and mobilized. The fistula is excised, and the muscle ends are then overlapped and sutured.

High fistulas and some mid-rectovaginal fistulas require a transabdominal approach. Simple fistulas with healthy surrounding tissues can be repaired by mobilization of the rectovaginal septum, division of the fistula, and layered closure of the rectal defect without bowel resection. If the local tissues are damaged by irradiation, infection, or inflammatory diseases, an extended low anterior resection with coloanal anastomosis should be performed.

Although most simple rectovaginal fistulas do not require a diverting colostomy, complex rectovaginal fistulas are best managed by a preliminary colostomy. For elderly or unfit patients, for most radiation-induced fistulas, and for rectovaginal fistulas associated with Crohn disease, a permanent colostomy may be prudent.

PILONIDAL SINUS

Pilonidal sinus is an acquired condition, beginning with rupture into the dermis of a hair follicle in the sacrococcygeal region. Why this happens at that location more than other locations, and what predisposes certain people (male sex, second or third decade of life, hirsute habitus, Mediterranean skin type) to develop pilonidal sinus is unclear. Although traditionally conceived as a solitary condition, pilonidal sinus is part of the *acne inversa* tetrad (hidradenitis suppurativa, acne conglobata, dissecting scalp perifolliculitis, and pilonidal sinus), and thus may be the most common manifestation of an incompletely penetrant syndrome. Acne inversa lesions indistinguishable from pilonidal sinus, but in other predictable locations such as the axillae, vulva, scrotum, and so on, are termed *hidradenitis suppurativa*, perhaps reflecting artificial distinctions between treating specialties rather than distinct disease processes. Pilonidal-like lesions have also been reported in unusual locations such as the umbilicus, healed amputation stumps, and interdigital clefts.

Clinical Manifestations

Pilonidal sinus typically begins as an acute abscess at the sacrococcygeal area that drains spontaneously or is drained surgically, leaving a nonhealing sinus with chronic drainage.

Diagnosis

A painful, fluctuant mass is typically the initial presentation. In its earliest stage, only cellulitis may be present, whereas in the chronic state one sees the sinus opening in the intergluteal fold, about 5 cm superior and posterior to the anus. Most sinus tracts run cephalad (93%); the rest run caudad (7%) and may be confused with anal fistula or suppurative hidradenitis. On careful examination, one can almost always find a pit or pits in the midline, representing ruptured hair follicles. The differential diagnoses include furuncles of the skin, anal fistula, syphilitic or tuberculous granulomas, and osteomyelitis with multiple draining sinuses in the skin. Actinomycosis in the sacral region has been described as virtually indistinguishable from pilonidal disease.

Treatment

Drainage of a pilonidal abscess can almost always be accomplished under local anesthesia. A longitudinal incision is made lateral to the midline over the abscess, and the cavity is entered. All hair in the abscess cavity, if present, is removed, and the wound is lightly packed. The patient is instructed to clean the wound at least once a day and to apply light packing. Antibiotics are not usually indicated.

For chronic pilonidal sinuses, the chronic cavity may be incised and the wound edges marsupialized. This is the time-honored

FIGURE 70.27. Endorectal advancement of anorectal flap. **A:** Exposure is gained by an anal speculum, and the fistula is identified. Outline of endorectal flap, extending proximally to 7 cm from the anal verge. **B:** The full-thickness flap is created to include the internal sphincter muscle. **C:** Lateral mobilization is made on each side in the submucosal plane. **D:** Anorectal wall on each side is approximated. **E and F:** The endorectal flap is pulled down to cover the wound and sutured. The fistula is excised. The aperture in the vagina is not sutured but is left open for drainage.

method, and healing is fairly reliable but sometimes prolonged. An alternative is to excise the sinus and perform a local flap repair.³⁸ Excellent results have been reported from specialty centers using this approach.

A third approach is the Bascom technique, which involves opening the main tract lateral to the midline. The sinus tracts to the midline pits are probed and laid open. Granulation tissue in the cavity is curetted and the wound packed. Healing is reported to be faster than for conventional excision, with the wound completely closed within 4 weeks in most cases.³⁹ Nonhealing or prolonged healing are problems with all conventional techniques, and there is a substantial corpus of literature on flap procedures for reclosing pilonidal wounds. The Bascom cleft-lift operation is also reported to work for failures of other techniques.⁴⁰

care, usually described as a critical feature of pilonidal care. However, general principles of open wound care seem to apply here as elsewhere: keeping the wound bed moist and the edges dry, gently debriding devitalized tissue and exudates, and removing foreign bodies.

SEXUALLY TRANSMITTED DISEASES OF THE ANORECTUM

The anus is part of the anogenital tract from the viewpoint of infectious diseases, which are substantially the same as those of the external genitalia.

Postoperative Care

Because of the high rate of nonhealing and prolonged healing in this area, much thought has been given to postoperative

Anal Condylomata Acuminata

9 Anal condylomata acuminata (warts) are caused by human papilloma viruses (HPV) of various subtypes. In most patients,

warts involve the perianal skin, anal verge, and anoderm. Occasionally, the lesions also involve the mucosa of the upper anal canal and the lower rectum, indicating that islands of squamous epithelium, the only type of epithelium HPV can infect, may be found in the upper anal canal and lower rectum as well. Extent of disease varies from a few small warts to a large mass that threatens to occlude the anus. The diagnosis is usually obvious by the characteristic papillary appearance. Anoscopic examination or palpation can detect intra-anal involvement. Because most cases are transmitted by sexual contact after a 1- to 3-month incubation period, other coexisting venereal diseases should be considered.

Small perianal warts can be destroyed by applying podophyllin, podophyllotoxin, bichloroacetic acid, or trichloroacetic acid. These are caustic agents, so uninvolved skin may be protected with petroleum jelly before application. Imiquimod, a topical interferon inducer, may be applied topically to anal margin warts. Extensive external warts, or any warts in the anal canal, are best treated by excision and fulguration with electrocautery. A laser may be used to excise and fulgurate warts, but there is no clear advantage over electrocautery.

Recurrence rates are greater than 65% in short-term studies, and one may reasonably assume that recurrence rates would be significantly higher with long-term follow-up. Immunotherapy with autogenous vaccine, injected interferon, or topical imiquimod in conjunction with excision and fulguration may be effective in delaying or reducing recurrence, but the role of these measures and their cost-effectiveness remain undetermined. The efficacy of HPV vaccination using the tetravalent vaccine in the prevention of anal warts is unknown. The vaccine is not effective therapeutically in patients who have already been infected.

Malignant transformation of condylomata acuminata is very rare and is usually associated with serotypes 16 and 18, although several other serotypes also have malignant potential. There is currently no role for serotyping HPV in clinical practice. Other risks for malignant transformation include longstanding condylomata and immunosuppression, either from transplantation or HIV. Malignant transformation is preceded by development of dysplastic changes (anal intraepithelial neoplasia, AIN), analogous to those seen in cervix (CIN), vulva (VIN), and vaginal dysplasia. Some authorities now recommend routine anal Papanicolaou smears for high risk (i.e., immunosuppressed) individuals. Using this approach, patients found to have high-grade dysplasia (AIN 2–3) undergo high-definition anal microscopy using a colposcope, with focal ablation of areas of high-grade dysplasia. Although several centers have reported encouraging results using this approach, proof of its efficacy in controlled trials is currently lacking.

When malignant transformation occurs, it is almost always to squamous carcinoma rather than adenocarcinoma. Malignancies are treated by location, with Nigro-type chemoradiation for anal canal lesions and surgical excision for anal margin lesions.

Gonococcal Proctitis

Patients with gonococcal proctitis are usually asymptomatic but may have mild anal burning, pain, discharge, or bleeding in the acute phase. Proctoscopy reveals inflamed anorectal mucosa with purulent discharge at the dentate line. In the chronic phase, the anus and rectum may appear normal. Diagnosis is confirmed by observing *Neisseria gonorrhoeae* on stained smears of the discharge, and by culture. In the United States, gonococcal antimicrobial resistance continues to evolve, and coinfection with *Chlamydia trachomatis* is found in up to 45% of gonorrhea cases.

The recommended treatment is a single injection of ceftriaxone plus a 7-day course of oral doxycycline, which is added for possible coexisting chlamydial infection. All patients treated

for gonorrhea should have a serologic test for syphilis, which if found can be treated with penicillin G. High-risk patients should be tested for HIV. Follow-up gonococcal cultures to confirm eradication are not necessary in the asymptomatic patient.

Chlamydial Proctitis

Chlamydia trachomatis is the most common cause of sexually transmitted disease in the United States, with about 4 million cases each year. Although most chlamydial infections affect the urethra, anorectal involvement is common when the anus is used sexually. Proctoscopy reveals a nonspecific inflammation, but immunofluorescence microscopy of swab material provides the diagnosis.

Treatment includes a 7-day course of oral tetracycline or doxycycline, which cures more than 95% of cases. Therefore, posttreatment cultures are not necessary. Erythromycins and fluoroquinolones are among the other effective antibiotics.

Herpes Simplex Proctitis

Anorectal herpes is caused by herpesvirus type II, the anogenital type. In herpetic proctitis, there may be severe anorectal pain, fever, inguinal lymphadenopathy, tenesmus, discharge, and bleeding. Examination reveals erythematous areas with small groups of vesicles that rupture and become ulcerated. Proctoscopy shows nonspecific proctitis,⁴¹ but Papanicolaou or Giemsa staining may show characteristic multinucleated giant cells, and the virus may be isolated from vesicle or ulcer fluid.

A 10-day course of oral acyclovir, valacyclovir, or famciclovir, especially if initiated shortly after the onset of lesions, is effective in limiting the extent and duration of symptoms. Topical acyclovir ointment has no significant effect on symptoms or healing time. Recurrent anorectal herpes, if symptomatic, is treated with shorter courses of the oral antivirals.

ANORECTAL DISEASES IN PATIENTS WITH HIV AND AIDS

Kaposi Sarcoma

Kaposi sarcoma (KS), associated with the herpesvirus HHV-8, is still one of the most common malignancies in AIDS patients. Because it thrives with low CD4 counts, the significance of KS is waning in the era of highly active antiretroviral therapy (HAART). Most colorectal KS is asymptomatic, but bleeding and obstruction may rarely occur; likewise, most KS of the anal verge and anal margin skin is asymptomatic. Treatment is directed at the HIV infection, and KS-specific treatment, if needed, is usually by radiation, chemotherapy, or other ablative measures.

Cytomegalovirus

Symptomatic cytomegalovirus (CMV) proctocolitis occurs in profoundly immunosuppressed AIDS patients. Like KS, CMV is waning in significance because of HAART. Symptoms of CMV proctocolitis include diarrhea, fever, abdominal pain, and weight loss. Proctoscopy may reveal sharply demarcated shallow ulcers with fibrinous exudate, and biopsy gives an accurate diagnosis. Treatment is directed at the HIV infection and the CMV infection. Because proctitis represents systemic infection, CMV is treated by oral or intravenous antivirals, depending on the severity of disease. When surgical complications such as perforation occur, they are usually intra-abdominal, not anorectal.

Lymphoma

Lymphomas occur at higher incidence in patients with HIV. Non-Hodgkin lymphoma was an original AIDS-defining diagnosis in the pre-HAART era, associated with low CD4 counts, whereas Hodgkin lymphoma occurs most commonly in patients with CD4 counts of 300 to 400. Anorectal lymphoma is usually extraluminal, sometimes presenting as perianal ulcer. Any atypical feature of a perianal ulcer in an HIV-positive patient should trigger a biopsy.

Anal Ulcers

Idiopathic anal ulcers were common among HIV-positive patients pre-HAART, and they are still found in AIDS patients with low CD4 counts. Most ulcers are in the posterior midline of the anal canal, straddling the dentate line and thus proximal to site of a typical anal fissure. They can be erosive, dissecting submucosally or intersphincterically, and creating painful areas of acute and chronic inflammation.⁴²

Examination of the anus and rectum under anesthesia is usually necessary. Biopsies should be taken and sent for viral, bacterial, and mycobacterial culture, dark-field examination for syphilis, and histopathologic examination to rule out CMV, lymphoma, and squamous cell cancer. About half of HIV-associated ulcers are specific, caused by syphilis, tuberculosis, HSV, cytomegalovirus, and other infections, and about half are nonspecific or idiopathic. Treatment of the latter has been empiric, using metronidazole and/or intralesional steroid injection; treating the HIV infection and raising the CD4 count addresses the underlying problem. Thalidomide has been reported to be effective treatment for HIV-associated aphthous ulcerations, and it might have a role in treating refractory anal ulcerations as well.⁴³

Anal Intraepithelial Neoplasia

HPV's role in AIN and anal cancers closely parallels its role in the genesis of cervical carcinoma, a more closely studied process. Oncogenic HPV strains such as 16 and 18 have a higher propensity to initiate the development of carcinoma.⁴⁴ These two well-studied serotypes also have a predilection for the less stable epithelium of the upper anal canal (transitional zone) rather than the modified skin of the lower anal canal (anoderm), but they can still be identified in the anal margin skin.

Anal carcinoma and its precursor lesion, anal intraepithelial neoplasia (AIN), both occur at markedly increased incidence in HIV-positive patients and in people with risk factors for HIV. This 'epidemic within the epidemic' is caused by oncogenic strains of HPV and indirectly facilitated by HAART, which has allowed patients to live long enough to develop these lesions. High CD4 counts are not protective. As HIV has become a chronic, manageable condition, anal carcinoma has become more common, necessitating the development of screening and surveillance regimens.⁴⁵

AIN can be detected using cytologic (Papanicolaou) smears, and positive findings can be followed by high-resolution anoscopy, using a colposcope and vital staining. In one prevalence study, AIN was present in 80% of HIV-positive men, and half of the AIN was high-grade (AIN II or III) (Fig. 70.28).⁴⁶ Low-grade AIN, like the condyloma it often accompanies, rarely undergoes malignant transformation and can be observed, or it can be ablated if symptomatic. High-grade AIN is the premalignant counterpart of anal squamous carcinoma, identical to carcinoma in situ and Bowen disease. Although the rate of malignant transformation is unknown, one can estimate that it is relatively low to date: Based on prevalence studies, roughly half of the 1,200,000 Americans living with HIV

FIGURE 70.28. High-grade anal intraepithelial neoplasia (Bowen disease, carcinoma in situ). Atypical epithelial cells involve the full thickness of the epidermis.

can be presumed to have high-grade AIN, and roughly half of the 5,000 new cases of anal canal cancer per year occur in HIV-positive patients. Thus about 2,500 cases arise annually in an at-risk population of about 600,000—about 0.4% per year. However, based on the analogy to CIN and cervical cancer, progression from high-grade AIN to anal cancer would be expected to take many years, and the incidence of anal cancer in HIV-positive patients may rise sharply with further years of observation on HAART therapy.

Many authors have recommended ablation of detectable lesions, and infrared coagulation is the currently favored ablative technique.⁴⁷ High-grade AIN is often very extensive and difficult to detect, so it may be very difficult to ablate completely; multiple treatments and persistence/recurrence are commonplace. Although all authors agree on aggressive treatment of invasive anal cancer (see later), there are many suggested strategies for managing high-grade AIN, from simple surveillance to aggressive ablation of all detectable lesions.^{48,49}

ANAL CANCER

Anal cancers—malignancies of the anal canal and the skin of the anal margin—are uncommon, and the literature is limited by nonuniform terminology and classification. The World Health Organization and the American Joint Committee on Cancer have developed standard terminology for neoplasms of the anal region.

Anal Intraepithelial Neoplasia in the HIV-negative Population

In the HIV-negative population, high-grade AIN (also called Bowen disease) is rare, slow growing, and can occur in any age group but is more prevalent in older women.⁵⁰ Immunosuppressed patients, especially those with solid organ transplants, are also a high-risk group for AIN. AIN may appear as a discrete scaly or crusted plaque; it may be pigmented; and it may be difficult to delineate. Biopsy of any atypical anal lesion is mandatory (Fig. 70.28). Once AIN has been detected, one may consider mapping the extent of nonvisible involvement by taking multiple biopsies, but there is no evidence that this practice improves patient outcomes. Once a patient has or has had AIN, lifetime surveillance is essential. Recurrences are reported as late

FIGURE 70.29. Photomicrograph of squamous cell carcinoma of the perianal skin. Note the presence of keratin.

as 9 years postoperatively; this is not surprising, because surgical intervention does not cure viral infection. Just as in the HIV-positive population, the value of colposcopy (high-resolution anoscopy) for surveillance is debated, and physical examination may be sufficient for detection of new, changed, or suspicious lesions. High-grade AIN in the HIV-negative population probably has a lower rate of malignant transformation than the same lesion in the HIV-positive population.

Squamous Cell Carcinoma

Squamous cell carcinomas of the anal margin resemble those occurring in skin elsewhere. They grow slowly and have rolled, everted edges and central ulceration. Any chronic unhealed or indurated ulceration in the perianal area should be biopsied, looking for squamous cell carcinoma (Fig. 70.29). Lymphatic spread from squamous carcinomas of the perianal area is mainly to inguinal lymph nodes. Despite their superficial location, most lesions are diagnosed late, with half of cases identified more than 22 months after the onset of symptoms; carcinoma is often discovered at a late stage (T3), measuring 5 cm or more. The importance of biopsying atypical ‘fissures’ and ‘external hemorrhoids’ cannot be overemphasized.

Wide local excision is the treatment for anal margin squamous cell carcinoma but only in properly selected cases. For microinvasive carcinoma and for cancers that do not invade muscle, local excision should be curative. For large, muscle-invasive (T4), or anal canal-invasive lesions, chemoradiation should be considered, as in anal canal cancer treatment. Abdominoperineal resection is rarely needed for anal margin cancer, though it may be used for patients with extensive lesions who cannot tolerate chemoradiation, or in patients with anal sphincter involvement and incontinence. Size of the carcinoma determines staging and prognosis, as of course do lymph node and distant-metastasis status. Five- and ten-year survival rates for T₁ lesions are both 100%, compared with roughly 60% and 40% for T₂ lesions.

Paget Disease

This intraepithelial adenocarcinoma was initially described in the breast. Extramammary Paget disease can be found in the anogenital region. Most authors agree that Paget cells are of glandular, probably apocrine, origin, from the adnexal organs

FIGURE 70.30. Perianal Paget disease. Paget cells are above the basal layer.

of the skin.⁵¹ Perianal Paget disease starts out as a benign in situ neoplasm, and it may eventually become invasive as an adenocarcinoma.

Paget disease occurs in the elderly, with an average age of 68.⁵² It appears as a slowly spreading pruritic and erythematous, sometimes sharply demarcated perianal rash that may ooze or scale. Because of its gross similarity to other conditions such as idiopathic pruritus ani and AIN, the diagnosis of perianal Paget disease is made by biopsy (Fig. 70.30) and is often delayed. In almost one third of the cases, the lesion involves the entire circumference of the perianal skin.

True Paget disease of the perianal skin must be distinguished from downward intraepidermal spread of a signet-ring cell adenocarcinoma of the rectum, which it resembles histologically. A complete colonoscopy with thorough examination of the rectum and anal canal should be performed. Synchronous visceral carcinomas have been found in up to 50% of patients.⁵³

In the absence of invasive carcinoma, wide excision with a microscopically clear margin is the treatment of choice. Because clinically invisible Paget disease may extend beyond the gross margin of the lesion, mapping the extent of involvement by obtaining biopsies in four quadrants at the dentate line, anal verge, and anal margin can assist with planning and establish a baseline for future surveillance. If extensive wide local excision is needed, reconstruction can be performed with large advancement or rotation flaps.⁵⁴

If there is a concomitant rectal adenocarcinoma, then treatment follows rectal cancer protocols, with the possible addition of inguinal lymph node dissection. Because diagnosis is delayed by an average of 4 years from onset of symptoms, about 25% of patients with invasive adenocarcinoma in Paget disease already have distant metastasis. Likely sites of metastasis are the same as those of any distal rectal adenocarcinoma.

Verrucous Carcinoma/Giant Condyloma

An overlapping group of entities is called *giant condyloma acuminatum*, *Buschke-Löwenstein tumor*, and verrucous carcinoma, although the term verrucous carcinoma is also used more broadly to describe a histologic subtype of squamous carcinoma. The giant condyloma is typically a large (>8 cm), slow-growing, symptomatic, warty growth with a soft feel and cauliflower-like appearance. It may arise in the anal margin skin or the anal canal and may be grossly and microscopically indistinguishable from very extensive condylomata acuminata.

Although it may be histologically bland, the lesion's behavior is clinically malignant.

These lesions may relentlessly expand and invade the ischioanal fossa, perirectal tissues, and even the pelvic cavity. Sinuses and fistula tracts may form and create complex lesion anatomy. Verrucous carcinomas rarely metastasize, but they do recur locally.

Treatment is wide local excision, which may even include abdominoperineal resection (APR), if the lesion involves the anal sphincters. Multimodality treatment may be considered.⁵⁵

Basal Cell Carcinoma

Basal cell carcinoma, elsewhere a lesion of sun-exposed skin, occurs rarely on the anal margin. It is usually superficial and rarely metastasizes. Treatment is wide local excision followed by surveillance, because local recurrence is a significant concern.⁵⁶

Anal Canal Neoplasms

Squamous Cell or Epidermoid Carcinoma. Squamous cell carcinoma of the anal canal has an incidence of about 5,000 cases per year in the United States, but this number increases every year with the HIV epidemic. Anal canal cancer differs in treatment and prognosis from anal margin cancer. Squamous cell or epidermoid cancer of the anal canal has various microscopic appearances, including large cell keratinizing (squamous), large cell nonkeratinizing (transitional), and basaloid. The term *cloacogenic carcinoma* has been used for the basaloid and large cell nonkeratinizing (transitional) form of epidermoid carcinoma. Most squamous cell carcinomas of the anal canal above the dentate line are nonkeratinizing (Fig. 70.31).

10 The presentation of epidermoid anal canal carcinoma is commonly a long history of anal problems misinterpreted as pruritus ani, hemorrhoids, or anal fissure, but now characterized by an indurated anal mass. Digital examination of the anal canal should demonstrate all but the smallest anal canal cancers, and the reader is reminded that a palpable 'hemorrhoid' requires biopsy—true internal hemorrhoids are not palpable. Anoscopy confirms digital findings and allows for biopsy.

Once anal canal cancer is diagnosed, colonoscopy is commonly done, but it is not strictly required as there is no association between epidermoid anal canal cancer and colorectal cancer. However, patients are often elderly, may have bled, or simply are due for colorectal cancer screening, so diagnostic

FIGURE 70.31. Squamous cell carcinoma of the anal canal. Note the absence of keratin.

colonoscopy is often indicated on its own merits. Computed tomography of the abdomen and pelvis is indicated for staging. Endoanal ultrasonography may be useful in evaluating depth of invasion (not part of anal canal cancer staging) and detecting perirectal lymph node metastasis. Enlarged or suspicious groin lymph nodes should be biopsied, either by excision or fine-needle aspiration, because reactive lymphadenopathy is common. Staging is detailed in Table 70.6.

Anal canal lymphatic pathways vary, and the pattern of spread depends on the location of the lesion. About 40% of lymph node metastases are in lymph nodes less than 5 mm in diameter,⁵⁷ suggesting a potential role for sentinel node biopsy in this condition.

Inguinal metastasis (stage III) is found in 15% to 20% of patients at the time of diagnosis and becomes apparent later in an additional 10% to 25%.⁵⁸ Screening of high-risk groups, such as patients with high-grade AIN (especially in the context of immunosuppression), should decrease the stage at which anal cancers are found. Alertness on the part of surgeons, when evaluating any patient for an atypical 'fissure' or 'hemorrhoid,' is another key defense against advanced disease. When anal cancer is less than 2 cm in diameter (T1), only 3% of patients are found to have lymph node metastasis, and the vast majority of these are curable. Although distant metastasis is uncommon at presentation, subsequent metastasis occurs frequently: 40% of the roughly 700 anal cancer-related deaths per year in the United States occur from disease outside the pelvis.

Treatment for all stages of anal canal cancer is by chemoradiation: The combination of 5-fluorouracil, mitomycin C, and pelvic radiation therapy was pioneered by Nigro in 1972.⁵⁹ Abdominoperineal resection had been standard treatment up to that point, but now the surgeon's role is to diagnose the lesion initially by biopsy, then reevaluate the scar 6 to 8 weeks after completion of chemoradiation to rule out persistent disease. Subsequent to Nigro's initial reports, prospective randomized trials established the most effective combination of chemoradiation for local control, avoidance of colostomy, and overall survival.⁶⁰ A typical modified Nigro regimen is summarized in Table 70.7; chemotherapy research continues, in the hope of replacing mitomycin C with a less toxic agent.⁶¹ Late adverse effects associated with radiation of the anal region include proctitis, diarrhea, incontinence, anal ulcers, and stenosis, leading to permanent colostomy in about 10% of patients.

Abdominoperineal resection continues to play a role for persistent or recurrent anal canal cancer. All studies of salvage abdominoperineal resection show better survival in recurrent than persistent disease, reflecting the natural history of the two types of lesion. Perineal wound problems are common from this operation, which always takes place in an irradiated field.⁶² As patients who undergo chemoradiation for anal cancer have a higher perineal wound complication rate following abdominoperineal resection than do those undergoing chemoradiation for rectal cancer,⁶³ primary reconstruction with a rectus abdominis myocutaneous flap should be considered.⁶⁴

Adenocarcinoma. Adenocarcinomas of the anus are rare, constituting 3% to 9% of all anal carcinomas.⁶⁵ The World Health Organization classifies these malignancies into rectal type, anal gland type, and anorectal fistula type.

Rectal Type. Rectal-type adenocarcinoma arises within the upper anal canal; histology is the same as rectal adenocarcinoma. It is impossible to distinguish this lesion from adenocarcinoma of the lower rectum.

Anal Gland Type. The anal gland ducts are lined by columnar epithelium with mucin-secreting (goblet) cells, from which mucoepidermoid carcinomas can arise. The characteristic feature of anal gland cancer is extramucosal adenocarcinoma without involvement of the anal canal surface epithelium, except where the lesion has spread locally.

TABLE 70.6 STAGING AND CLASSIFICATION

AMERICAN JOINT COMMITTEE ON CANCER STAGING CLASSIFICATION FOR SQUAMOUS CELL CARCINOMA OF THE ANAL CANAL

PRIMARY TUMOR (T)	
Tx:	Primary tumor cannot be assessed
T0:	No evidence of primary tumor
Tis:	Carcinoma in situ
T1:	Tumor 2 cm or less in greatest dimension
T2:	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3:	Tumor more than 5 cm in greatest dimension
T4:	Tumor of any size invades adjacent organ(s), e.g., vagina, urethra, bladder (involvement of sphincter muscle alone is not classified as T4)
REGIONAL LYMPH NODES (N)	
Nx:	Regional lymph nodes cannot be assessed
N0:	No regional lymph node metastasis
N1:	Metastasis in perirectal lymph node(s)
N2:	Metastasis in unilateral internal iliac and/or inguinal lymph nodes
N3:	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes
DISTANT METASTASIS (M)	
Mx:	Distant metastasis cannot be assessed
M0:	No distant metastasis
M1:	Distant metastasis
STAGE GROUPING	
Stage 0	Tis, N0, M0
Stage I	T1, N0, M0
Stage II	T2, N0, M0 T3, N0, M0
Stage IIIA	T1, N1, M0 T2, N1, M0 T3, N1, M0 T4, N0, M0
Stage IIIB	T4, N1, M0 Any T, N2, M0 Any T, N3, M0
Stage IV	Any T, Any N, M

TABLE 70.7 TREATMENT

MODIFIED NIGRO REGIMEN FOR SQUAMOUS CELL CARCINOMA OF THE ANAL CANAL

TREATMENT	DOSE	SCHEDULE
External radiation	50 Gy, to the primary carcinoma and 35–45 Gy to pelvic inguinal nodes	Start day 1 (2 Gy/d, 5 d/wk for 5 wk)
Systemic chemotherapy	Fluorouracil, 1,000 mg/m ² /24 h as a continuous infusion for 4 d	Start day 1; repeat 4-d infusion starting day 28
Mitomycin C	10–15 mg/m ² as intravenous bolus	Day 1 only

Anorectal Fistula Type. Mucinous adenocarcinoma may arise within long-standing anorectal fistula tracts. Some authors believe that they originate in the anal glands and ducts, suggesting that the distinction between anal gland-type and anorectal fistula-type adenocarcinoma may be artificial.

Rectal-type adenocarcinoma of the anal canal is treated according to rectal cancer protocols, with local or radical excision depending on depth of invasion, as determined by endoluminal ultrasound or MRI. Abdominoperineal resection is the definitive treatment for most anal canal adenocarcinoma. Although chemoradiation is definitive treatment for epidermoid anal canal cancer, adenocarcinomas of the anal canal are less responsive to nonsurgical therapy.⁶⁶

Melanoma. Melanoma accounts for less than 1% of anal canal malignancies. However, the anal canal is the third most common site for melanoma, after skin and eyes. The female-to-male ratio is approximately 2:1, and the average age at presentation is 63 years.

One should suspect melanoma when one sees a deeply pigmented 'hemorrhoid' causing symptoms. However, most anal melanomas are lightly pigmented or frankly amelanotic, so they are often misdiagnosed as polyps or squamous cell carcinomas. Examination under anesthesia and incisional or excisional biopsy allows for correct diagnosis.

Anal canal melanomas spread submucosally into the rectum but rarely invade adjacent organs, possibly because most patients die before this can occur. Lymphatic spread to mesenteric nodes is seen in about one third of patients at the time of diagnosis; spread to inguinal nodes is less common. Wide hematogenous spread, especially to liver and lung, is common, accounting for most deaths.

Anal canal melanomas do not respond to chemotherapy, radiotherapy, or immunotherapy. While surgery is the only option, it is almost never curative, and abdominoperineal resection confers no survival benefit compared with wide local excision.⁶⁷ Sometimes wide local excision involves destroying the anal sphincters, so it must be accompanied by diverting colostomy; when the tumor is large, abdominoperineal resection may be the best option for obtaining local control. Sentinel node excision, a staple of cutaneous melanoma surgery, has not been explored in this population.

CHAPTER 71 ■ ABDOMINAL WALL HERNIAS

ROBERT J. FITZGIBBONS Jr., SAMUEL CEMAJ, AND THOMAS H. QUINN

KEY POINTS

- 1 Surgeons have traditionally been taught the anatomy of the abdominal wall from an outside to inside perspective. However, with the increasing use of intra-abdominal or preperitoneal approaches to abdominal wall reconstruction, a better understanding of the anatomy from the inside to the outside perspective is important.
- 2 Type I collagen is responsible for tensile strength, while type III collagen is less mature and is most important in the early phases of wound healing. A decreased ratio of type I to type III collagens can be detected in fascial and skin specimens obtained from patients with hernias.
- 3 Inguinal hernias constitute approximately 75% of abdominal wall hernias, with femoral hernia accounting for 5%. Incisional, umbilical, and epigastric hernias account for 15% and miscellaneous hernias make up the other 5%.
- 4 Watchful waiting is an acceptable alternative to routine repair for male inguinal hernia patients with minimal symptoms. This does not apply to females because of the higher risk of a hernia accident.
- 5 The performance of a “tension-free” inguinal hernia repair dramatically reduces the risk of recurrent hernia to a rate generally reported to be less than 2%.
- 6 The most popular laparoscopic techniques for repair of an inguinal hernia are the transabdominal preperitoneal repair and the totally extraperitoneal laparoscopic repair.
- 7 Historical recurrence rates of 30% to 40% following ventral hernia repair have been dramatically reduced by modern tension-free repairs.
- 8 A recent major prospective, randomized, multicenter trial showed that laparoscopic repair was associated with a significantly increased risk of recurrent hernia than open repair (10.1% vs. 4.9%).
- 9 The frequency of at least some long-term groin pain may be as high as 50% at 1 year following inguinal hernia repair with moderate to severe pain in up to 10% of patients.
- 10 Ischemic orchitis occurs in about 1% of primary hernia repairs but is more common following repair of a recurrent hernia.

One of the most frequently performed operations by general surgeons worldwide is the repair of an abdominal wall hernia. According to the National Center for Health Statistics, in the United States in the year 2003, the number of hernia repairs by type was 770,000 inguinal, 175,000 umbilical, 105,000 incisional, 30,000 femoral, and 80,000 miscellaneous (epigastric, spigelian, etc.), for a total cost of approximately \$2.5 billion, assuming a conservative estimate of a base cost of \$2,000 to \$2,500 per procedure.¹ In the past, most training programs relegated the repair of abdominal hernias to the junior members of the surgical team with little regard for results.² However, in the modern era of heightened emphasis on accountability to our patients, this is changing rapidly. Interest by the academic community in the science behind hernia repair as well as an explosion in device development by industry has resulted in significant changes in many surgeons' practices. This chapter describes these recent changes in the approach to hernia repair.

ANATOMY OF THE ABDOMINAL WALL AND GROIN

The anatomy of the abdominal wall and the inguinal region are presented, first from the viewpoint of the surgeon using open techniques and subsequently from the perspective of the surgeon utilizing the laparoscope. Anatomic terms for which synonyms and eponyms are commonly used are listed in Table 71.1. Specific anatomic nomenclature can now be found in *Terminologia Anatomica*, the successor to *Nomina Anatomica*.

The abdominal wall spans the gap between the lower ribs and the pelvis; the lowest ribs, pelvic brim, and lumbar spine comprise its only skeletal support. The muscular and aponeurotic

structures that provide much of the integrity of the wall must not only compress and contain abdominal viscera but also contribute to the support and movement of the spine and pelvis.

The sheets of relatively thin muscles and aponeuroses that make up the abdominal wall would, individually, seem to predispose to visceral eventration. However, the laminar layout of these sheets over most of the wall precludes this in most cases. The most common sites of hernia formation are found between laminations, where only peritoneum and fascia are found between the viscera and skin. These weak areas are most important to the hernia surgeon and are described in detail in the subsequent sections dealing with the anterior and posterolateral abdominal wall and the inguinal region.

Anterior Abdominal Wall

Superficial Fascia, Vessels, and Nerves. The anterior abdominal wall does not consist solely of muscle and aponeurosis; it can also be the repository for copious amounts of adipose tissue (panniculus adiposus) in its superficial fascial layer, often called *Camper fascia*. This layer, which is continuous inferiorly with the outer layer of fascia covering the perineum and genitalia, also contains the dartos muscle fibers of the scrotum. The major blood vessels of the superficial fatty layer are the superficial epigastric vessels and superficial circumflex iliac vessels, which are tributaries of the femoral vessels. The superficial fascia is also replete with lymphatic vessels that drain into the inguinal lymph nodes inferior to the umbilicus. The lymphatic structures cross the inguinal ligament, so that they are potentially placed in the surgical field during open herniorrhaphy.

TABLE 71.1**ANATOMIC TERMS WITH COMMON SYNONYMS AND EPONYMS****FASCIAL STRUCTURES/SPACES**

Fatty layer of superficial fascia; panniculus adiposus; Camper fascia

Investing fascia of external abdominal oblique; fascia innominata

Membranous layer of superficial fascia; Scarpa fascia

Retroinguinal space; space of Bogros

Retropubic space; space of Retzius

LIGAMENTOUS STRUCTURES

Iliopectineal ligament; iliopectineal arch

Iliopubic tract; Thompson ligament (band)

Inguinal ligament; Poupart ligament

Lacunar ligament; Gimbernat ligament

Pectineal ligament; Cooper ligament

APONEUROSIS-DERIVED STRUCTURES

Arcuate line; semicircular line; linea semicircularis; line of Douglas

Falx inguinalis (often incorrectly referred to as *conjoined tendon*)

Reflected inguinal ligament; reflex ligament; Colles ligament

Semilunar line; linea semilunaris; Spigelius line

A second fascial layer in the superficial abdominal wall is the deep fascia of Scarpa. Although most commonly considered a distinct anatomic layer, Scarpa fascia actually consists of compressed fibrous components of the superficial fascia.³ The deeper fibrous tissue of the superficial fascia forms the fundiform ligament of the penis (suspensory ligament of the female clitoris), continues onto the penis and scrotum, and ultimately fuses with the superficial fascia of the perineum.

The superficial fascia also fuses with the layer of fascia (fascia innominata) investing the external abdominal oblique muscle. This fascia is bound inferiorly to the inguinal ligament and pubis before continuing onto the thigh, where it blends with the fascia lata to seal the space beneath and inferior to the

inguinal ligament, which is the inferior portion of the myopectineal orifice (Fig. 71.1). This portion of the inguinal region includes the Hesselbach (inguinal) triangle superiorly and therefore constitutes the weakest aspect of the groin.

The skin of the anterior abdominal wall is segmentally innervated in the familiar dermatome pattern. The nerve branches to this area are derived from the anterior and lateral cutaneous branches of the ventral rami of the 7th to 12th intercostal nerves and from the ventral rami of the first and second lumbar nerves. Disruption of one of these nerves is rarely noted by the postoperative patient because the dermatome fields overlap significantly. The anterior and lateral cutaneous branches reach the subcutaneous layer by coursing between the flat lateral muscles and by piercing the sheath of the rectus abdominis.

Anterior Musculature and Ligaments. The division of the wall into anterior and posterior segments is somewhat artificial because the anterior muscles, with the exception of the rectus abdominis, arise posteriorly and also form part of the posterior wall.

The three muscles of the lateral aspect of the anterior abdominal wall (Fig. 71.2) are composed of a variable amount of muscle with a large aponeurosis. The aponeurosis is the tendon of insertion for the lateral muscles, and it also forms the sheath of the rectus abdominis. The midline decussation of the three aponeuroses forms the linea alba. Fibrous tissue layers are of great importance to the hernia surgeon because of their ability to support sutures. *Fascia* and *aponeurosis* are terms commonly used to describe these fibrous structures but are often confused and used interchangeably. In this chapter, an aponeurosis is defined as the non-muscle-fiber-containing portion of a muscle usually present at insertion points. Muscle fibers are said to “give way” to the corresponding aponeurosis. Fascia, on the other hand, is the fibrous tissue that lines or envelops muscles.

External Abdominal Oblique Muscle and Associated Ligaments. The external abdominal oblique muscle (Figs. 71.2 and 71.3A, B) is the most superficial of the three lateral abdominal muscles. The external abdominal oblique arises from the posterior aspects of the lower eight ribs and interdigitates with both the serratus anterior and the latissimus dorsi at its origin. The direction of the muscle fibers varies from nearly horizontal in its upper portion to oblique in the middle and lower portions. The mostly horizontal fibers, which originate posteriorly, insert onto the anterior portion of the iliac

FIGURE 71.1. The myopectineal orifice. Superior to the inguinal ligament, this area includes the inguinal (Hesselbach) triangle. Inferior to the ligament, the orifice transmits the iliopsoas muscle, the femoral nerve and vessels, and the femoral canal and sheath. FIGURE 71.2. Pattern of crossing of the aponeurotic fascicles of the abdominal wall musculature. A: Fascicles from the right external oblique and anterior lamina of the left internal oblique. B: Fascicles from the right transversus abdominis and posterior lamina of the left internal oblique. C: Fascicles between the right and left transversus abdominis muscles.

crest. The obliquely arranged anteroinferior fibers of insertion fold on themselves to form the inguinal ligament. The remaining portion of the aponeurosis inserts into the linea alba after contributing to the anterior portion of the rectus abdominis sheath. Some fibers cross the linea alba to reinforce further the anterior rectus sheath of the opposite side.

The more medial fibers of the aponeurosis of the external oblique divide into a medial and a lateral crus to form the external or superficial inguinal ring. The spermatic cord (or round ligament) and branches of the ilioinguinal and genitofemoral nerves pass through this opening. The *inguinal ligament* (Fig. 71.4) is worthy of special consideration because of its important role as both a landmark and an integral component of many groin hernia repairs. The inguinal ligament is formed by obliquely oriented anteroinferior aponeurotic fibers of the external abdominal oblique. The ligament is formed when the aponeurosis folds beneath itself. Its lateral attachment is to the anterior superior iliac crest; its medial insertion is primarily on the pubic tubercle.

The medial insertion of the inguinal ligament in most persons is dual. One portion runs along the superior surface of the pubic tubercle and symphysis to form (or at least reinforce) the superior pubic ligament. The other portion is fan shaped and spans the distance between the inguinal ligament proper and the pectineal line of the pubis. This fan-shaped portion of the ligament is called the *lacunar ligament* (Fig. 71.4). It blends laterally with the pectineal (Cooper) ligament.

Internal Abdominal Oblique Muscle and Aponeurosis.

The middle layer of the lateral abdominal group is the internal abdominal oblique muscle (Figs. 71.2 and 71.3B, C). This muscle primarily arises from the iliac fascia along the iliac crest and forms a band of iliac fascia fused with the inguinal ligament. The uppermost fibers course obliquely toward the distal ends of the lower three or four (“floating”) ribs. The muscle fibers of the internal oblique fan out following the shape of the iliac crest, so that the lowermost fibers are directed inferiorly. These fibers arch over the round ligament, or spermatic cord. Some of the lower muscle bundles in the male join fibers of the transversus abdominis to form the cremaster muscle. The aponeurosis of the internal oblique (Fig. 71.5A) above the level of the umbilicus splits to envelop the rectus abdominis, re-forming in the midline to join and interweave with the fibers of the linea

alba. Below the level of the umbilicus (Fig. 71.5B), the aponeurosis does not split but rather runs anterior to the rectus muscle, continues medially as a single sheet, joins the anterior rectus sheath, and finally contributes to the linea alba. The aponeurotic portion of the internal oblique is widest at the level of the umbilicus.

Transversus Abdominis Muscle and Aponeurosis.

The transversus abdominis muscle (Figs. 71.2 and 71.3C) arises from the fascia along the iliac crest and inguinal ligament and from the lower six costal cartilages and ribs, where it interdigitates with the lateral diaphragmatic fibers. The muscle bundles of the transversus abdominis for the most part run horizontally. The lower medial fibers, however, may continue in a more inferomedial course toward the site of insertion on the crest and pecten of the pubis.

The aponeurosis of the transversus abdominis joins the posterior lamina of the internal abdominal oblique, forming above the umbilicus a portion of the posterior rectus sheath. Below the umbilicus, the transversus abdominis aponeurosis is a component of the anterior rectus sheath. The gradual termination of aponeurotic tissue on the posterior aspect of the rectus abdominis forms the arcuate line (of Douglas) (Fig. 71.6). The medial aponeurotic fibers of the transversus abdominis insert on the pecten pubis and the crest of the pubis to form the *falx inguinalis*. These fibers infrequently are joined by a portion of the internal oblique aponeurosis; only then is a true conjoined tendon formed.⁴

The arch formed by the termination of the aponeurotic fibers of the transversus abdominis is called the *aponeurotic arch* (Fig. 71.6). The area beneath the arch varies. A high arch may be a predisposing factor in direct inguinal hernia. Contraction of the transversus abdominis causes the arch to move down toward the inguinal ligament in a kind of shutter mechanism, which reinforces the weakest area of the groin when intra-abdominal pressure is raised.

Rectus Abdominis. The rectus abdominis (Figs. 71.3D and 71.5) forms the central and anchoring muscle mass of the anterior abdomen. The rectus muscle arises from the fifth to the seventh costal cartilages and inserts on the pubic symphysis and pubic crest. Each rectus muscle is segmented by tendinous intersections at the levels of the xiphoid process and the

FIGURE 71.3. A: External oblique muscle and aponeurosis. B: Internal oblique muscle and aponeurosis. C: Transversus abdominis muscle and aponeurosis. D: Lower rectus abdominis and pyramidalis muscle. The linea alba is formed by the intermeshed fibers of the aponeuroses of the lateral muscle layers; it is tensed by the pyramidalis, which inserts into it.

umbilicus and at a point midway between these two. The principal blood supply reaches the muscle from the superior and inferior epigastric arteries (Fig. 71.5), which anastomose just superior to the umbilicus. Other vessels are anterior branches of the intercostal arteries; these reach the muscle by entering the lateral aspect of the rectus sheath. The innervation of the muscle is from the 7th to the 12th intercostal nerves, which

laterally pierce the aponeurotic sheath of the muscle. The lateral edge of the muscle is demarcated by a slight depression in the aponeurotic fibers coursing toward the muscle; this depression is the *semilunar line*.

The small pyramidalis muscle (Fig. 71.3D) accompanies the rectus abdominis at its origin in a minority of people. The pyramidalis arises from the pubic symphysis. It lies within the rectus

FIGURE 71.4. Ligamentous structures of the inguinal region. The iliopubic tract is not seen in this view because it is obscured by the inguinal ligament. The lacunar ligament is the expanded medial end of the inguinal ligament; on the pecten pubis, it blends with the inguinal (Cooper) ligament.

sheath and tapers to attach to the linea alba, the conjunction of the two rectus sheaths and the major site of insertion of three aponeuroses from all three lateral muscle layers.

Rectus Sheath. Although the components of the rectus sheath individually have been discussed in relation to the three lateral abdominal muscles, it should also be considered as a distinct entity. Three features of the rectus muscle and its sheath can be observed even topographically in well-muscled or very thin subjects:

1. The semilunar line is a slight depression in the aponeurotic fibers corresponding to the lateral edge of the rectus muscle. It marks the site of initial lateral insertion of the aponeurotic tendons of the lateral abdominal muscles.

2. The tendinous inscriptions divide each muscle into three parts.⁵ These are the basis of the expression “six pack,” popularized by bodybuilders.
3. The linea alba is the midline confluence of the aponeuroses of the rectus muscles and also the internal and external oblique muscles.

The composition of the rectus sheath varies depending on the level sampled. The anterior sheath superior to the umbilicus is composed of the aponeurosis of the external abdominal oblique and the anterior lamina of the internal abdominal oblique. The transversalis aponeurosis does not participate in the formation of the anterior sheath at this level. At a variable level inferior to the umbilicus, the anterior sheath is a composite of all the aponeurotic layers.

The posterior sheath of the rectus muscle superior to the umbilicus is a lamination of the posterior lamina of the aponeurosis of the internal abdominal oblique and the transversus abdominis aponeurosis. The external abdominal oblique does not participate in the formation of the posterior portion of the rectus sheath. At a highly variable site inferior to the umbilicus, all the aponeurotic tendons pass anteriorly to form the anterior rectus sheath. The fibers of the posterior sheath are seen to attenuate gradually. The aponeurotic fibers do not end abruptly at the arcuate line. This transfer of connective tissue away from the posterior rectus sheath causes the arcuate line (of Douglas) to form on the posterior surface of the muscle (Fig. 71.6). The tissue covering the deep surface of the rectus muscle inferior to the arcuate line is primarily the transversalis fascia.

Some have questioned this traditional scheme of rectus sheath composition, contending that each of the aponeurotic layers superior to the umbilicus is actually bifid, with both contributing to the anterior and posterior sheaths.⁶ The fibers of the posterior sheath are seen to attenuate gradually. The concept of rectus sheath composition favored by most is shown in Figure 71.7.

Innervation and Blood Supply of the Anterior Abdominal Wall. The innervation of the anterior wall muscles is multiple. The lower intercostal and upper lumbar nerves (T7 to T12, L1, L2) contribute most of the innervation to the lateral muscles and to the rectus abdominis and overlying skin. The nerves pass anteriorly in a plane between the internal abdominal oblique and the transversus abdominis, eventually piercing the lateral aspect of the rectus sheath to innervate the muscle therein. The external oblique muscle receives branches of the intercostal nerves, which penetrate the internal oblique. The anterior ends of the nerves form part of the cutaneous innervation of the abdominal wall. The first lumbar nerve

FIGURE 71.5. **A:** Immediately superior to the umbilicus, the rectus sheath consists of anterior and posterior components. The anterior sheath is composed of the aponeuroses of the external and internal abdominal oblique muscles, and the posterior sheath consists of the posterior aponeurotic lamina of the internal oblique and the aponeurosis of the transversus abdominis muscle. **B:** The rectus sheath inferior to the arcuate line (of Douglas) consists of an anterior portion made up of fibers from all aponeurotic layers; the posterior portion at this point comprises only transversalis fascia covered internally by peritoneum.

FIGURE 71.6. The deep inguinal region, pelvis, and anterior abdominal wall from the viewpoint of a surgeon using a laparoscopic technique. The anterior wall folds upward approximately at the iliopubic tract in this illustration.

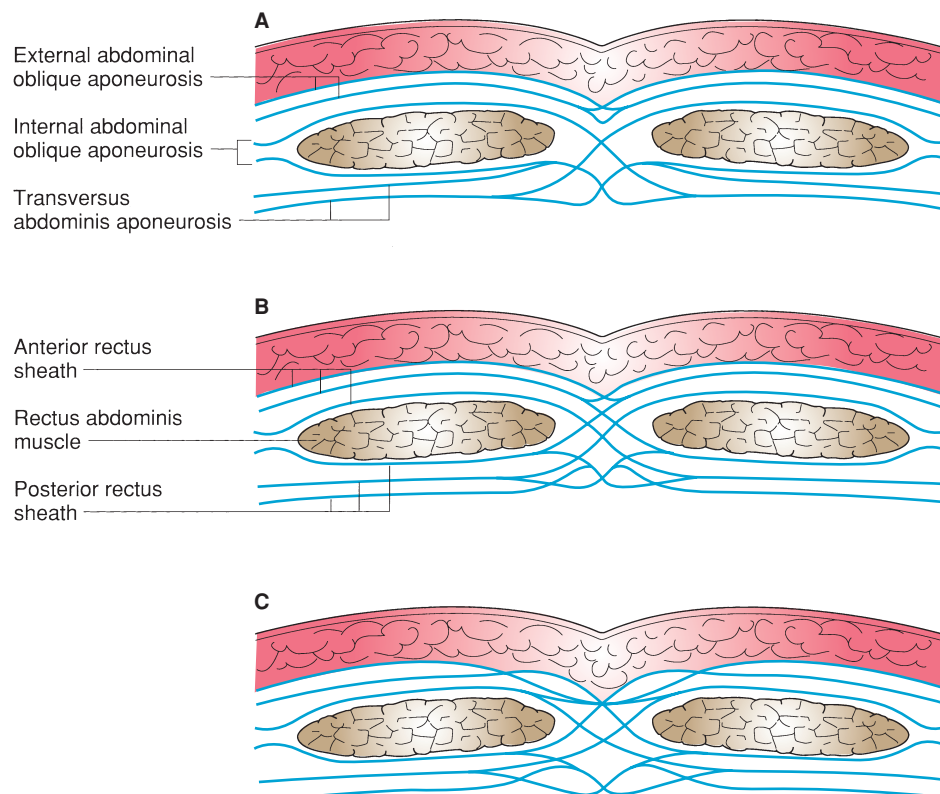

FIGURE 71.7. Patterns of midline decussation of the aponeuroses. **A:** Single anterior and posterior lines of decussation. **B:** Single anterior and triple posterior lines of decussation. **C:** Triple anterior and posterior lines of decussation. (Adapted from Askar O. Surgical anatomy of the aponeurotic expansions of the anterior abdominal wall. *Ann R Coll Surg Engl* 1977;59:313.)

divides into the ilioinguinal and iliohypogastric nerves. These may divide within the psoas major muscle or between the internal oblique and transversus abdominis muscles. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique. The ilioinguinal nerve then passes through the external inguinal ring to run with the spermatic cord, whereas the iliohypogastric nerve pierces the external oblique to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve (L1, L2).

The blood supply of the lateral muscles of the anterior wall is primarily from the lower three or four intercostal arteries, the deep circumflex iliac artery, and the lumbar arteries. The rectus abdominis has a complicated blood supply derived from the superior epigastric artery (a terminal branch of the internal thoracic, or internal mammary, artery), the inferior epigastric artery (a branch of the external iliac artery), and the lower intercostal arteries. The latter arteries enter the sides of the muscle after traveling between the oblique muscles. The superior and inferior epigastric arteries enter the rectus sheath and anastomose near the umbilicus.

Posterolateral (Lumbar) Abdominal Wall

The posterolateral or lumbar portion of the abdominal wall (Fig. 71.8) often is overlooked in discussions of abdominal hernia, perhaps because of the much more common occurrence of groin and femoral hernias. The configuration of the muscle layers in the lumbar area also predisposes to hernia formation. For the purposes of this discussion, the lumbar portion of the abdominal wall is defined as the area bounded superiorly by the 12th rib, inferiorly by the iliac crest, and medially by the erector spinae group. Eight muscles arrayed in three layers constitute the posterolateral or lumbar portion of the abdominal wall.

The most superficial layer is composed of the external abdominal oblique muscle, which arises from the posteroinferior portion of the lower ribs and inserts in part along the posterior iliac crest. Closely associated with the external oblique in this area is the latissimus dorsi, which arises from the poste-

rior iliac crest, the spinous processes of the sacrum and lumbar vertebrae, and the lumbodorsal fascia. The muscle courses obliquely toward its insertion on the medial aspect of the intertubercular groove of the humerus. The triangular space formed by the two muscles just described and the iliac crest is called the *inferior lumbar (Petit) triangle* (Fig. 71.8A).

The middle layer of lumbar abdominal muscles consists of the erector spinae, the internal abdominal oblique, and the extremely thin insignificant serratus posterior inferior. The erector spinae forms a significant portion of the abdominal wall in the lumbar region, with fibers extending nearly the length of the spinal column. The internal abdominal oblique muscle forms the remainder of the layer. The serratus posterior inferior arises from the lumbodorsal fascia and inserts on the lower four ribs. The middle layer of lumbar muscle is associated with the superior lumbar triangle, a more common site of hernia than the inferior lumbar triangle described previously. The superior triangle (Fig. 71.8B) is formed superiorly by the 12th rib, the serratus posterior inferior, and the superior lumbocostal ligament; inferiorly by the upper border of the internal abdominal oblique; and medially by the erector spinae.

The deep layer of the lumbar abdominal wall includes three muscles: the quadratus lumborum, the psoas major, and the transversus abdominis. The quadratus lumborum primarily arises from the posterior iliac crest and inserts on the 12th rib. The psoas major arises from vertebrae T12 through L5 and passes beneath the inguinal ligament to insert on the lesser trochanter of the femur.

Deep Inguinal Region

Laparoscopic View

1 **Deep Aspect of the Anterior Abdominal Wall, Peritoneal Folds, and Associated Structures.** If one creates a space in the abdominal cavity by distending it with gas, an excellent view of the anterior wall can be obtained. The umbilical peritoneal folds (Fig. 71.9) in most subjects are very prominent and provide easily identified landmarks. The folds (ligaments) primarily exist because the peritoneum covers underlying structures.

FIGURE 71.8. The lumbar abdominal wall with the inferior lumbar triangle (A) and the superior lumbar triangle (B).

FIGURE 71.9. The deep inguinal region and the anterior abdominal wall seen from within the abdomen. The urachus, the obliterated portion of the umbilical artery, and the inferior epigastric vessels are covered by peritoneal folds, respectively called the median, medial, and lateral umbilical folds.

The single median umbilical fold extends from the umbilicus to the urinary bladder and covers the urachus, the fibrous remnant of the fetal allantois. The urachus may be patent for a short distance in adults or may open into the umbilical scar in newborns. The medial umbilical fold is formed by the underlying obliterated portion of the fetal umbilical artery. This normally cordlike structure, like the urachus, may be patent for a portion of its length. Indeed, the proximal, patent portion of the artery normally supplies the superior vesicular arteries to the bladder. The lateral fold covers the inferior epigastric arteries as they course toward the posterior rectus sheath, which they enter approximately at the level of the arcuate line.

Between the median and the medial ligaments, a depression is usually found that is called the *supravesical fossa*. This is the site of hernias of the same name. The fossa formed between the medial and lateral ligaments is the medial fossa; this is the site of direct inguinal hernias. The lateral fossa is less well delineated than the others. The medial border of the fossa is formed by the lateral umbilical ligament and the rectus abdominis. This fossa does not have a lateral border; rather, the concavity slowly attenuates. The deep inguinal ring is located in the lateral fossa and therefore is the site of the congenital or indirect inguinal hernia.

Transversalis Fascia. The transversalis fascia (endoabdominal fascia) is perhaps the most commonly misunderstood structure in the literature devoted to groin hernia. Confusion results because surgeons may actually be referring to very different anatomic structures when discussing various hernia repairs; however, each may use the same anatomic term or eponym. Indeed, perhaps the biggest reservation among surgeons intent on performing a Shouldice repair is a precise definition of what is being sewn to what.

The transversalis fascia proper is a continuous sheet that extends throughout the extraperitoneal space. The term *transversalis fascia* generally is defined as the deep or endoabdominal fascia covering the internal surface of the transversus abdominis, the iliacus, the psoas muscles, and the obturator internus and portions of the periosteum. One variant of this convention is the use of terms specific to the muscle covered by the fascia (e.g., iliac fascia).

Most authors feel that only one layer of transversalis fascia exists, whereas others maintain that the transversalis fascia comprises two layers, or laminae.⁸ The posterior lamina is a layer of fibrous connective tissue that widely varies in density and continuity and is interspersed with adipose tissue, as seen in Figure 71.10. This layer is often referred to simply as the *preperitoneal fascia*. The anterior lamina is more uniform and is adherent to the deep surface of the transversus abdominis and the rectus abdominis. The posterior lamina is contained within the preperitoneal space, which is defined as the space between the peritoneum and the anterior lamina of the transversalis fascia. The inferior epigastric vessels are enclosed by, or interspersed with, the adipose tissue and the fibrous tissue of the posterior lamina of the transversalis fascia. The vessels are in contact anteriorly with the anterior lamina of the transversalis fascia as they course upward to enter the rectus abdominis sheath.

Transversalis Fascia Derivatives. The transversalis fascia analogues or derivatives are the iliopectineal arch, iliopubic tract, and crura of the deep inguinal ring. The superior and inferior crura form a transversalis fascia sling, a structure shaped like a “monk’s hood,” around the deep inguinal ring (Fig. 71.9). The transversalis fascia also contributes the internal spermatic fascia to the spermatic cord at this point. This “sling” has functional significance; when the transversus

FIGURE 71.10. A parasagittal section through the layers of the anterior abdominal wall and groin. Observe that the transversalis fascia is depicted as a bilaminar structure.

abdominis contracts, the crura of the ring are pulled upward and laterally, which results in a valvular action that helps to prevent the indirect formation of a hernia.

The iliopubic tract (Figs. 71.9 and 71.11) has become an increasingly important landmark for surgeons as the use of laparoscopic technology has increased.^{9,10} The iliopubic tract is the thickened band of transversalis fascia formed at the zone of transition between the deep surfaces of the iliac and transversus

abdominis muscles. The structure courses parallel to the more superficially located inguinal ligament, is attached to the iliac crest laterally, and inserts on the pubic tubercle medially. The tract forms along its course a portion of the inferior crus of the deep inguinal ring and then contributes to the anterior and medial walls of the femoral sheath. The tract fuses with the inguinal ligament to form a component of the inferior wall of the inguinal canal. At its insertion on the pubic tubercle, it curves backward slightly to blend with the Cooper pectineal ligament. The pectineal ligament actually is a condensation of periosteum and is not a true analogue of the transversalis fascia, but it is reinforced by fibers from the iliopubic tract and inguinal ligament.

The iliopubic tract contains not only fibrous connective tissue but also some elastic fibers.¹¹ In one series, the iliopubic tract was a substantial structure, suitable for use in hernia repairs, in 42% of the specimens examined. The tract, whether substantial or not, can be used as a readily identified landmark.

The iliopubic tract has particular significance because of its importance as a landmark to the laparoscopic surgeon. Many of the branches of the lumbar plexus run inferior to the tract, and damage to these nerves may be the result of aggressive dissection or the placement of tacks or staples to affix a prosthesis below this structure. The tract is not obviously visible in every patient from a laparoscopic view, but its location should always be immediately known to the surgeon because of its constant relationship to the other landmarks in this area.

The iliopectineal arch (Fig. 71.9) is also a condensation of the transversalis fascia. The iliopectineal arch commences at the medial border of the iliacus muscle, where it is continuous with the iliac fascia, itself a portion of the transversalis (endoabdominal) fascia. The arch separates the vascular compartment containing the femoral vessels from the neuromuscular compartment containing the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The iliopectineal arch also contributes to the proximal portion of the femoral sheath, thereby joining the iliopubic tract in the formation of the femoral sheath.

Femoral Sheath, Canal, and Ring. The femoral sheath (Fig. 71.12) is composed primarily of extensions of the transversalis fascia. The sheath is best understood in terms of the

FIGURE 71.11. A schematic representation of the deep inguinal region. The iliopubic tract is shown as a thickening of the transversalis fascia, inferior to which many of the branches of the lumbar plexus exit the pelvis.

FIGURE 71.12. Schematic view of the femoral sheath, ring, and canal. The transversalis fascia forms the anterior portion of the sheath, and the iliopsoas fascia forms the posterior portion. Septa separate the vessels from each other and the vein from the femoral canal. The femoral ring contains a lymph node. The ring is formed medially by the aponeurosis of the transversus abdominis aponeurosis, anteriorly by the inguinal ligament, posteriorly by the pubic bone, and laterally by the femoral sheath.

structures contained within. As the external iliac artery and vein pass beneath the inguinal ligament to become the femoral vessels, they are covered anteriorly by the transversalis fascia proper. This fascial layer is posteriorly and laterally joined by portions of the iliopsoas fascia, which are themselves continuations of the transversalis fascia. At the inguinal ligament, the iliopsoas fascia forms the iliopectineal arch. This arch divides the vascular compartment (lacuna vasorum), containing the femoral vessels, from the muscular portion (lacuna musculorum), which contains the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The vascular lacuna is further divided by septa into compartments for the vessels and the femoral branch of the genitofemoral nerve.

The medial border of the femoral sheath follows the transversus abdominis aponeurosis to its insertion just lateral to that of the lacunar ligament and extends inferiorly to fuse eventually with the medial septum and adventitia of the femoral vein. The resultant cone-shaped cul-de-sac is the femoral canal. The canal normally contains only wisps of connective tissue and small lymphatic nodes. The wider proximal part of the canal, the femoral ring, contains a large node, which is often referred to as the *Cloquet node*.

The femoral ring is the extraperitoneal opening of the canal. The boundaries of the ring are formed medially by the curved edge of the transversus abdominis aponeurosis, not the lacunar ligament, which inserts more medially.¹² Laterally, the ring is bounded by the connective tissue septum and the adventitia that is interposed between it and the femoral vein. The anterior boundary is the inguinal ligament; posteriorly, the ring is reinforced by the iliopubic tract and iliopectineal ligament. The canal is not in direct communication with the pelvic cavity. The transversalis fascia is not a component of the roof of the canal because it is diverted at this point to form the femoral sheath. This weakened area is therefore quite prone to hernia formation, especially in female subjects.

Inguinal (Hesselbach) Triangle. The inguinal triangle is the site of direct inguinal hernias. This triangle is most often described from the anterior aspect (Fig. 71.13), in which case the inguinal ligament forms the base of the triangle, the rectus abdominis the medial border, and the inferior epigastric vessels the superolateral border. The triangle as originally described by Hesselbach had the pectineal ligament as its base. The latter description is quite useful to the surgeon viewing the abdomen from within because the inguinal ligament cannot be seen from this viewpoint. When the inguinal triangle is transilluminated, the thinness and translucency of the area of abdominal wall within the triangle underscores its importance in hernia development and repair. In the most translucent area, little or no

muscle is present. Only the peritoneum and the transversalis fascia cover the triangle here. The aponeurotic arch of the transversus abdominis crosses the triangle just below the apex in most people. A high aponeurotic arch affords less reinforcement to the triangle and may therefore predispose a person to the formation of a direct inguinal hernia.

Components of the Spermatic Cord. The spermatic cord (Figs. 71.11 and 71.14) is closely associated with the deep inguinal ring. The spermatic cord is most appropriately described at this point because the deep ring itself is formed by derivatives of transversalis fascia, as is the innermost covering layer of the spermatic cord, the internal spermatic fascia. The middle covering layer is called the *cremasteric fascia* and contains the cremasteric muscle bundles; both are derived from the internal abdominal oblique muscle and fascia. The outermost covering of the spermatic cord is the external spermatic fascia, which is continuous with the investing fascia of the external abdominal oblique muscle.

The tunica vaginalis is initially a component of the cord, but normally it atrophies and closes early in neonatal life. This

FIGURE 71.13. The inguinal (Hesselbach) triangle.

FIGURE 71.14. The component layers covering the contents of the spermatic cord.

structure is an evagination of peritoneum. The testicle descends retroperitoneally in fetal life and is merely in contact with the posterior aspect of the tunica. An indirect congenital hernia enters the patent tunica vaginalis.

The cord structures enclosed by the coverings described earlier are the ductus (vas) deferens, the pampiniform venous plexus, the testicular artery, and the genital branch of the genitofemoral nerve, a branch of the lumbar plexus (Figs. 71.9, 71.11, and 71.15).

Branches of the Lumbar Plexus. The nerves crossing the iliac fossa are some of the most variable in the body. This variability may be the cause of frequent intraoperative injury to the fragile nerves. The lumbar plexus is formed by roots from the 12th thoracic nerve and the first through fourth lumbar nerves. Cutaneous territories innervated by branches of the lumbar plexus are seen in Figure 71.15A. The five terminal branches commonly encountered in laparoscopic herniorrhaphy can be discerned in many people as they course

FIGURE 71.15. A: The cutaneous territories innervated by several branches of the lumbar plexus. B: Some of the branches of the lumbar plexus seen from within the abdomen.

across the iliacus muscle covered by peritoneum and the iliac fascia (a portion of the transversalis-endopelvic fascia). The nerves form within or deep to the psoas major muscle (Fig. 71.15B), often ramifying with other nerves within or close to the muscle. The nerve branches initially lie within the so-called triangle of pain,¹³ bordered medially by the psoas muscle, anteriorly and inferiorly by the iliopubic tract, and laterally by the iliac crest. With the exception of the genital branch of the genitofemoral nerve, the branches of the lumbar plexus destined for the thigh run beneath the iliopubic tract.

The most anterior of the nerves encountered, the genitofemoral nerve, is also the most variable. This nerve may occur as a single trunk lying deep to the peritoneum and fascia on the anterior surface of the psoas muscle. The nerve may also divide into its component genital and femoral branches within the muscle. The genital branch travels with the spermatic cord, entering at the deep inguinal ring; it ultimately innervates the cremaster muscle and the lateral scrotum. The femoral branch of the nerve innervates the skin of the proximal mid thigh.

The lumbar plexus branch encountered immediately deep to the lateral aspect of the psoas muscle is the large femoral nerve. Although not routinely encountered during laparoscopy, the femoral nerve has been injured in some cases.¹⁴ The lateral femoral cutaneous nerve crosses the iliac fossa under the iliac fascia to run deep to the iliopubic tract and the inguinal ligament, which it pierces to enter the thigh.

The iliohypogastric nerve typically arises with the ilioinguinal by a common trunk from the first lumbar nerve. They may exchange fibers within the muscle, but they usually diverge immediately to form individual nerves. The iliohypogastric nerve crosses the iliac fossa just inferior to the kidney and pierces the transversus abdominis. The subsequent course of the nerve carries it between the transversus and the internal abdominal oblique until it pierces the aponeuroses of both obliques just above the external inguinal ring.

The ilioinguinal nerve normally crosses the iliac fossa just inferior to the iliohypogastric nerve. In its typical further course, the nerve pierces the transversus abdominis and internal abdominal oblique above the iliac crest and eventually enters the inguinal canal. The nerve may run more diagonally through the iliac fossa and then pierce the iliopubic tract to reach the inguinal canal.¹⁵ This path “can obviously render the nerve more vulnerable to iatrogenic injury.”¹⁵

Vasculature of the Abdominal Wall and Deep Inguinal Region

The vasculature of the deep inguinal region and anterior abdominal wall has been analyzed by surgeons for well over 100 years. The importance and variability of these vessels have been underscored by the ominous mnemonics used to refer to them—“crown of death” (*corona mortis*) and “triangle of doom.” The primary blood supply to the deep anterior wall is from the inferior epigastric artery. This artery is a branch of the external iliac artery. In many cases, an artery called the “aberrant” obturator artery arises from the inferior epigastric, which joins the “normal” obturator artery and thereby forms a circle—the *corona mortis*—before entering the obturator foramen. Injury to the circle, usually sustained while the surgeon is working in the area of the Cooper ligament, causes copious bleeding. Recent studies have indicated that aberrant obturator vessels are present in between 60% and 90% of whole pelves studied.^{16,17}

The veins in this area also are prone to injury because many, especially the iliopubic veins and obturator veins and their tributaries, may be much larger than their accompanying arteries. One network of veins in the area is situated on the inferior deep surface of the rectus muscles. The veins of this

network, which anastomose with the pubic branches discussed earlier, have been called the *rectusial veins*.¹⁸

The vessels in the vascular compartment of the deep inguinal region are the external iliac artery and vein. They arise within a triangular area bordered laterally by the gonadal vessels and medially by the ductus deferens. The primary continuations of the external iliac vessels are the femoral artery and vein. The inferior epigastric artery is a branch of the external iliac. The obturator artery may arise from either of these arteries as a replacement or accessory to the obturator branch of the internal iliac artery.

A final vessel to consider in this review is the deep circumflex iliac artery (Fig. 71.10). The origin of this artery is extremely variable, but its course is predictable along the iliopubic tract. It pierces the transversalis fascia and runs along the iliac fossa to anastomose eventually with a deep lumbar artery. Because the deep circumflex artery runs along the iliopubic tract, it can inadvertently be stapled or otherwise injured during laparoscopic herniorrhaphy.

Pelvic Floor and Obturator Muscles

The pelvic musculature normally affords remarkable support to the structures within the true pelvis. Although a myoaponeurotic hammocklike sheet forms the pelvic diaphragm, obturator muscles and membrane, and urogenital diaphragm, herniation of fat or viscera through or around any of these layers occurs. The potential for hernia formation is increased because of the openings through which many structures exit or enter the pelvis.

The Latin term *obturator* is translated as “stopper for a bottle.” The aptly named obturator internus, along with its membrane and the obturator externus, closes off nearly all the large obturator foramen. The small superolateral aperture through which the obturator vessels and nerve pass is the site where obturator hernias form. The obturator internus arises from the deep surface of parts of all three pelvic bones. The muscle fibers converge on a tendon, which leaves the pelvis through the lesser sciatic foramen to insert on the greater trochanter. The dense internal obturator fascia covers the muscle and is thickened to form the arcuate ligament, from which the levator ani muscles (the pelvic diaphragm) are in part suspended. The obturator internus fascia splits to enclose the pudendal vessels in the pudendal canal. The external obturator muscle arises from the pelvic bones surrounding the obturator foramen and from the anterior portion of the obturator membrane. The external obturator muscle is supplied by the obturator nerve and vessels.

The component muscles of the bowl-shaped pelvic diaphragm, the pubococcygeus, iliococcygeus, and puborectalis, along with the coccygeus form the floor of the pelvis. The pubococcygeus arises from the posterior aspect of the pubis and the thickened portion of the internal obturator fascia, called the *tendinous arch* (Fig. 71.16), that spans the distance between the pubis and ischial spine. The puborectalis, the midportion of the diaphragm, arises from the pubis and loops around the rectum as the puborectal sling. The iliococcygeus is suspended at its origin from the tendinous arch and inserts on the coccyx. The coccygeus muscle completes the diaphragm posteriorly, arising from the ischial spine and inserting on the sides of the coccyx.

The area remaining between the sacrum and the greater sciatic foramen is filled for the most part by the piriformis muscle. The piriformis arises from the anterior surface of the second through fourth sacral vertebrae and the sacrotuberous ligament. This muscle exits the pelvis through the greater sciatic foramen, which is thereby divided into suprapiriform and infrapiriform portions (Figs. 71.16 and 71.17). The superior gluteal nerves and vessels pass through the suprapiriform foramen, whereas the inferior gluteal nerves and vessels in company with the sciatic nerve pass through the infrapiriform foramen.

FIGURE 71.16. A: The pelvic diaphragm (levator ani and the piriformis) and the urogenital diaphragm viewed from within the pelvis. B: Hemisection of the pelvis revealing the levator ani, piriformis, obturator internus, and psoas muscles.

The most pronounced deficit in the pelvic diaphragm is situated anteriorly, where an aperture must allow the urogenital structures to pass out of the pelvis. This area is reinforced by the urogenital diaphragm, a structure primarily consisting of the superficial and deep transverse perineal muscles. The deep transverse perineal muscle is enclosed by a weak superior fascia and a sturdier inferior perineal fascia. The urogenital diaphragm recently has been shown to be more funnel shaped than sandwichlike, as previously depicted in many atlases. The urogenital diaphragm exists only in humans because the human pelvic outlet faces inferiorly, unlike that of quadrupeds.

WHY DO HUMAN BEINGS DEVELOP ABDOMINAL WALL HERNIAS?

The most common hernias develop at sites where the abdominal wall has natural openings such as the internal inguinal ring, the umbilicus, and the esophageal hiatus. Previous surgical entry sites (incisional hernia) are also common areas where

hernias develop. Factors that increase the pressure in the abdominal cavity, such as obesity, heavy lifting, coughing with chronic lung disease, straining during a bowel movement or urination (prostatism), chronic lung disease, and ascites, have traditionally been considered important in the etiology, especially at these natural openings. Developmental phenomena also play a role. For example, in the evolution from a quadruped to a biped, the unprotected groin is more vulnerable to changes in intra-abdominal pressure, predisposing to inguinal herniation. The role of heavy lifting, especially a single strenuous event, is an unsettled question and has considerable medical-legal ramifications. There is minimal evidence that vigorous abdominal wall activity is an independent risk factor for abdominal wall hernia development despite the overwhelming opinion to the contrary in the lay literature.^{19,20} Indeed, there is not an excessive incidence of hernias in athletes and weightlifters. Nevertheless, there remain some proponents to the theory.²¹

2 Imbalances in collagen, the basic building block of the abdominal wall, are believed to contribute to hernia disease. While type I collagen confers predominantly tensile strength, type III collagen consists of thinner fibers and is regarded as a temporary matrix during tissue remodeling. A decreased ratio

FIGURE 71.17. The gluteal muscles and lateral rotators of the hip. External relations of the sciatic foramen are also evident.

of type I to type III collagens can be detected in fascial and skin specimens obtained from patients with hernias. Familial predisposition and the role of connective tissue diseases in hernia development have received considerable attention in recent years. Various connective tissue disorders, such as osteogenesis imperfecta, Marfan syndrome, Ehlers-Danlos syndrome, and congenital hip dislocation, are associated with hernias. A similar phenomenon was discovered by Cannon and Read in smokers when they performed biopsies of the rectus sheaths from adult smokers with inguinal hernias and coined the term “metastatic emphysema.”²² The investigators also demonstrated significantly greater levels of circulating serum elastolytic activity in patients who smoke.

Recent studies dealing with the development of a hernia have focused on the extracellular matrix (ECM). The ECM is in a dynamic balance of synthesis and degradation by matrix metalloproteinases (MMPs). MMPs are zinc-dependent proteases secreted as latent proenzymes with substrate specificity.²³ Studies by Bellon et al. revealed an MMP-2 overexpression in fibroblasts of patients with direct inguinal hernias, while Klinge et al. detected MMP-13 overexpression in patients with recurrent inguinal hernias.^{24,25}

COMPLICATIONS OF HERNIAS

Hernia Accident

For years surgeons have been taught that all hernias should be repaired at diagnosis to prevent a hernia accident, which is defined as a bowel obstruction or incarceration with strangulation, because of the perception that patients presenting with these complications have an unacceptable increase in mortality. This thinking, however, has not stood up when tested in randomized controlled trials. For example, for men with asymptomatic inguinal hernias, randomized controlled trials have shown that a strategy of watchful waiting is safe.²⁶

Incarceration

Incarcerated means “trapped” or “imprisoned.” Clinically, an incarcerated hernia is an irreducible hernia. An incarceration is not in and of itself a surgical emergency. Many hernias are chronically incarcerated due to adhesions of contents (e.g., omentum, bowel, ovary, etc.) to the hernial sac. The hernia itself is not necessarily tense to palpation, and the overlying skin appears normal. Normal bowel sounds may be heard within the hernia. It is important to differentiate an incarcerated hernia from a hydrocele of the cord. One can get above the hydrocele with the examining fingers. One cannot get above a hernia, however, as it communicates with the abdominal cavity. A hydrocele will transilluminate clearly, but a hernia will not.

An acutely incarcerated, painful hernia must be managed carefully. An attempt at reduction is reasonable unless there are signs of strangulation, which is not always obvious by clinical examination. Immediate surgical exploration is the safest approach when the diagnosis is not clear. The advantage of reduction followed by elective repair is that edematous tissue associated with an acute incarceration can return to normal, which presumably will translate into a better repair with less chance of infection.²⁷ If an attempt at reduction seems reasonable, the patient is sedated and placed in bed. The Trendelenburg position should facilitate reduction of a groin hernia. An attempt should be made at the initial examination to reduce the hernia. The maneuver of taxis entails grasping the neck of the hernia with the fingers of one hand and then applying intermittent pressure on the most distal part of the hernia with the other hand. Taxis has the effect of elongating the neck of the hernia so that the contents of the hernia may be guided through this area back into the abdominal cavity with a rocking movement. Mere pressure on the most distal part of the hernia causes bulging of the hernial sac around the neck, which can occlude the neck and prevent it from being reduced (Fig. 71.18). The maneuver of taxis should not be performed with excessive

FIGURE 71.18. Reduction of a hernia by taxis. **A:** Applying pressure on the hernia directly occludes the neck. **B:** Elongating the neck of the hernia while applying pressure allows reduction.

pressure or too vigorously. If the hernia is strangulated, gangrenous bowel might be reduced into the abdomen or perforated in the process. One or two gentle attempts should be made at taxis. If they are unsuccessful, this procedure should be abandoned. Rarely, the hernia together with its peritoneal sac and constricting neck may be reduced into the abdomen (reduction en masse). The patient would then have persistent obstruction after reduction of the hernia.

Intestinal Obstruction

One hundred years ago, the most common cause of intestinal obstruction was a hernia. At the present time, hernia is third, after adhesive obstructions and cancer. Hernia is an important cause of obstruction that is not infrequently missed on clinical examination. When a patient with an intestinal obstruction is examined, great emphasis should be placed on adequate exposure of the entire abdominal wall and groin area (from nipples to knees). Proper lighting is essential because previous scars can fade with time and become barely perceptible. The patient with intestinal obstruction as a result of a hernia will have a tense hernia that is irreducible. The abdomen itself will be distended, and high-pitched bowel sounds with frequent rushes will be heard. If the process continues to the complication of strangulation, these signs will disappear. Unlike adhesive small-bowel obstructions, partial small-bowel obstructions secondary to hernia are rare. Most patients will have had vomiting and obstipation.

A plain roentgenogram of the abdomen will reveal the signs of an intestinal obstruction—dilated loops of bowel with air-fluid levels and no bowel gas distal to the obstruction. Frequently on a plain roentgenogram, one can see bowel shadows in the region of the hernia. A lateral view is often useful to demonstrate this feature more clearly. Contrast studies are not usually necessary in this instance. Computed tomography (CT) reliably demonstrates the hernia with characteristic features of obstruction and should be considered if the clinical diagnosis is not certain (Fig. 71.19) because a distal intestinal obstruction secondary to another cause (e.g., adhesions) may result in significant distention of a coincidental nonobstructing hernia of the abdominal wall. Should the examiner focus attention exclusively on the hernia, the real cause of the obstruction may be missed when the hernia is repaired.

The next steps in management include resuscitation followed by urgent surgery. At surgery, an approach directly over the hernia is used. In all patients, the entire gastrointestinal tract must be assessed to eliminate causes of obstruction other than the hernia itself. This is done before the hernia is repaired. The bowel, if viable, is reduced into the abdomen. If difficulty is encountered in reducing the hernia, the neck of the hernia can be widened. In the case of an inguinal hernia, division of the neck with or without ligation and division of the inferior

epigastric vessels is safe, and the hernia contents can be reduced into the abdomen. In the case of a femoral hernia, the inguinal ligament can be split anteriorly and the hernia contents reduced into the abdomen. If the bowel is nonviable, then a bowel resection can be performed with anastomosis. The hernia is then repaired.

Strangulation

Strangulation of a hernia is a serious and life-threatening condition in which the hernial contents become ischemic and nonviable. The pathogenesis of this condition involves intra-abdominal contents within the hernia sac. Straining may push more contents into the sac, and the tense sac then causes pressure at the neck. This pressure initially produces venous congestion, resulting in edema. Eventually, the pressure is so great that the arterial supply is obstructed and the contents become gangrenous.

When intestine is involved, in addition to having an irreducible hernia and intestinal obstruction, the patient is toxic, dehydrated, and febrile. Examination of the abdomen reveals the signs of an intestinal obstruction, with distention and increased bowel sounds. Absolute constipation and vomiting are other manifestations. The hernia itself is tense, irreducible, and very tender, and the overlying skin may be discolored with a reddish or bluish tinge. No bowel sounds are heard within the hernia itself. The patient commonly manifests a leukocytosis with a predominance of polymorphonuclear leukocytes. Blood gases may reveal metabolic acidosis.

FIGURE 71.19. Computed tomogram showing a left-sided inguinal hernia.

FIGURE 71.20. Richter hernia. Part of the bowel wall herniates through the defect in the abdominal wall.

Management of these patients requires urgent attention to detail. No attempt should be made to reduce the hernia. Rapid resuscitation should commence immediately, with nasogastric suction and replacement of fluids and electrolytes. The patient should be given antibiotics. Once the patient is resuscitated, urgent surgery commences to expose the hernia, open the sac, and assess the viability of the bowel. More bowel can be pulled into the hernia so that viable bowel can be transected and the gangrenous portion removed. An end-to-end anastomosis should be performed and the bowel then reduced into the abdominal cavity. The hernia is then repaired.

Richter Hernia

August Gottlob Richter in 1785 described a hernia type that bears his name in which the antimesenteric border of the intestine protrudes into the hernia sac without involving the entire circumference of the intestine, so intestinal obstruction does not occur (Fig. 71.20). The most common site is the femoral ring (36% to 88%), followed by the inguinal canal (12% to 36%) and an abdominal wall incision (4% to 25%). Miscellaneous locations include umbilical, obturator, suprapubic, spigelian, triangle of Petit, sacral foramen, Morgagni, internal, and (traumatic) diaphragmatic.²⁸ The routine use of laparoscopy by general surgeons has resulted in an increased incidence at trocar sites such that most surgeons will repair the fascia for trocar sleeves greater than 5 mm. The surgical treatment is to expose the herniated bowel by opening the sac. The neck of the sac is enlarged to allow delivery of the bowel into the wound. Any areas of gangrene are excised and the bowel wall reconstituted. The hernia is then repaired.

Massive Hernia

Abdominal wall hernias with a large portion of the abdominal contents situated within the sac are said to have “loss of domain” because the contents of the hernia exceed the capacity of the abdominal cavity. Forced reduction of the hernia with replacement of contents into the abdominal cavity and repair of the hernia can increase intra-abdominal tension tremendously, resulting in respiratory insufficiency or abdominal compartment syndrome.²⁹ In extreme cases, it is impossible to return the contents to the abdomen and repair the hernia defect without resection of intra-abdominal contents, such as colectomy with omentectomy. Complications of repair are common and include respiratory compromise, abdominal compartment syndrome, skin flap necrosis, and wound infection, in addition to the usual surgical complications. Therefore, repair should not be recommended unless there are overwhelming indications such as disabling symptoms, bowel obstruction or strangulation, or extensive skin ulceration caused by the hernia.

Progressive preoperative pneumoperitoneums can be useful in these patients to expand the abdominal cavity by stretching the abdominal wall and the diaphragm.²⁹ The maneuver involves injecting 500 to 1,500 mL of air every 1 to 3 days for about 3 weeks before the repair. A variety of access techniques have been described including direct puncture with a Veress needle, minilaparotomy with placement of a dialysis-type catheter, and the use of an implantable vascular access device with the catheter placed in the peritoneal cavity.³⁰ Although theoretically attractive, pneumoperitoneum is not always successful. The injected gas sometimes preferentially enters the hernia sac and distends it with minimal effect on the abdominal cavity. In addition, pneumoperitoneum has been shown to diminish lower extremity venous return. This could translate into a higher risk of thromboembolic complications. Deep venous thrombosis prophylaxis is prudent.

A combination of the techniques described later in this chapter for the repair of ventral hernias is usually required. Large pieces of prosthetic material with or without component separation are useful. A staged procedure has been described in which a large prosthesis is sewed to the circumference of the hernia defect and the skin and subcutaneous tissues closed over it. The prosthesis is purposely placed under some tension to cause “medialization” of the abdominal wall. The patient is returned to the operating room on a scheduled basis and the center portion of the prosthesis is removed and the edges reapproximated. The goal is to eventually be able to close the fascia primarily, usually with an underlay prosthesis.³¹

Prosthetic Materials. The development of a wide variety of materials that can be used for abdominal wall reconstruction now makes it possible to individualize the selection of prostheses so that they can be used in almost all clinical situations. The materials that have the longest track record for routine use in hernia surgery include polypropylene, either monofilament (Marlex, Prolene) or polyfilament (Surgipro); Dacron (Mersilene); and expanded polytetrafluoroethylene (ePTFE) (Gore-Tex). Polypropylene or Dacron work by inciting an intense fibroplastic response to form a strong scar plate interface. Because of this response, they should not be used in situations where contact with intra-abdominal viscera cannot be avoided because of the propensity of these materials to erode into intra-abdominal organs, most commonly intestine, resulting in fistulization. Either a nonmesh material such as ePTFE or a dual-layered prosthesis with a standard plastic mesh on the side facing the abdominal wall with the peritoneal side coated with an adhesion barrier of some type should be used. Recently, a number of dual-sided prosthetics have been introduced with a variety of adhesion barriers (Table 71.2). ePTFE and the adhesion barrier products are effective in decreasing both the amount and tenacity of adhesion, but none can completely eliminate them. Absorbable prostheses such as polyglactin are not durable and almost never result in long-term correction of

an abdominal wall defect but are sometimes useful as a temporary substitute when a nonabsorbable prosthesis is contraindicated (i.e. a grossly infected wound).

The role of the newer biologic prostheses is yet to be determined. Currently available products have been derived from human, porcine, or fetal bovine skin; porcine small intestine submucosa; and bovine pericardium. These materials are processed to remove hair, cells, and cell components as well as other antigens present in the matrix, leaving only the highly organized collagen architecture with the surrounding extracellular ground tissue.³² These biologic tissue grafts are designed to perform as a surgical prosthesis for soft tissue repair. In general, they possess the physical and mechanical characteristics of a clinically acceptable surgical mesh in that they promote strong tissue in-growth that limits contraction and have sufficient mechanical strength to withstand the physiologic and anatomic stresses of the abdominal wall, at the same time presenting a biologic scaffold to support tissue regeneration.

At the present time best indication for the newer biologic prostheses is contaminated wounds, where a synthetic prosthesis is contraindicated. They are not useful in grossly infected wounds presumably because of the high collagenase content present, which destroys them. A more contentious issue is the routine use for abdominal wall reconstruction. The argument

for them is that by remodeling to more normal tissue rather than simply inciting scar tissue as with the plastic meshes, they are more physiologic. It is theorized that this might translate into fewer long-term complications (e.g., postherniorrhaphy wound pain). The argument against them is their expense, as they generally cost 20 to 30 times that of the plastic prostheses. Widespread adoption of these biologic grafts cannot be justified unless there is overwhelming evidence of their superiority. Randomized controlled studies both for inguinal and incisional hernias are now ongoing.

The weight of the polypropylene or polyester meshes, as well as the size of the pores, is a controversial issue currently. As an example, a 7.5 × 15-cm polypropylene mesh (Prolene, Ethicon, Inc.) contains about 80 g/m² of polypropylene, while a recently developed polypropylene–poliglecaprone-25 lightweight mesh of the same size (Monocryl, UltraPro, Ethicon, Inc.) contains less than 30 g/m² after absorption of the poliglecaprone-25 component. One of the ways of reducing the amount of nonabsorbable material in a mesh is to increase the size of the pores. Many authorities believe that the inflammatory response incited by the small-pore, heavyweight plastic meshes can lead to chronic pain; a sensation of being able to feel the mesh; increased stiffness of the abdominal wall with loss of compliance; and shrinkage, which can lead to recurrence. There is

increasing evidence that decreasing the density of polypropylene and increasing the size of the pores reduces this foreign body response, resulting in less long-term pain than normal mesh and at the same time affording the patient a similar recurrence rate.^{33–35} This also addresses a theoretical concern about the possible carcinogenic effects of polypropylene, as has been suggested by experimental studies in rats (although there has never been a documented case of a sarcoma developing in a human as a result of an inguinal hernia prosthesis).³⁶

GROIN HERNIAS

Hernias are described as inguinal and femoral, the inguinal hernias being further subdivided into direct and indirect hernias (some authorities refer to these as medial and lateral hernias, respectively). Groin hernias may be primary or recurrent. An indirect hernia occurs as a protrusion of abdominal contents through the internal ring, lateral to the inferior epigastric vessels, into the inguinal canal. Indirect inguinal hernias (lateral hernias) are situated within the spermatic cord and therefore may extend into the scrotum. In female patients, the hernia follows the round ligament and may present as a swelling in the labium. A direct hernia (medial hernia) is a protrusion through the triangle of Hesselbach medial to the inferior epigastric vessels. These hernias develop through an area where the endoabdominal fascia is not protected by overlying muscle. Direct hernias do not usually involve the cord, as they tend to protrude forward. However, they occasionally track alongside the cord down the entire length of the inguinal canal and even enter the scrotum. For this reason, the only absolute distinction between a direct and an indirect hernia is the relationship to the inferior epigastric vessels. A femoral hernia protrudes through the femoral canal, which is bordered by the inguinal ligament superiorly, the pubic ramus medially and inferiorly, and the femoral vein laterally. This hernia presents below the inguinal ligament (Fig. 71.21). In a sliding hernia, part of the sac is formed by the viscera, on the left side the sigmoid colon or bladder and on the right side the cecum or bladder (Fig. 71.22).

Epidemiology

- 3 Inguinal hernias occur in persons of all ages, from the neonate to the elderly. The incidence of inguinal hernias in premature babies is approximately 10%. The lifetime risk of developing a groin hernia is between 15% and 25% in males and less than 5% in females. Right-sided inguinal hernias are more common than left. The male-to-female ratio for inguinal hernias is 7:1,

FIGURE 71.21. A: Inguinal hernia. This presents above the inguinal ligament and extends below it. B: Femoral hernia. This presents below the inguinal ligament.

FIGURE 71.22. Sliding hernia (right indirect inguinal).

with 8% of groin hernia repairs performed in women. Femoral hernias account for fewer than 10% of all groin hernias; however, 40% present as emergencies, with incarceration or strangulation, and mortality is higher for emergency repair than for elective repair. In men, indirect inguinal hernias outnumber direct by about 2:1, with femoral hernias making up a much smaller proportion. For females, indirect inguinal hernias are most common, followed by femoral hernias, with direct hernias occurring rarely. Emergency operations are required more frequently in females. A study from the Swedish Hernia Registry analyzing 90,648 inguinal hernia operations (88,753 male, 6,895 female) between 1992 and 2003 revealed a higher percentage of emergency operations in women (16.9%) than men (5%), leading to bowel resection in 16.6% and 5.6%, respectively.³⁷ Femoral recurrences were particularly common in females in whom the diagnosis at the time of the primary repair was direct or indirect (4.6% male, 41.6% female), strongly suggesting a missed hernia at the original procedure. Femoral hernias are also more common in older patients and in those who have previously undergone inguinal hernia repair.

Classification

The primary purpose of a classification system for any disease is to stratify for severity so that reasonable comparisons can be made between various treatment strategies.³⁸ However, with the multiplicity of operative techniques and approaches for repair of groin hernias, no one classification system has been accepted by all practitioners. The reason why it is so difficult to develop a classification system that all surgeons can agree on is that in the final analysis, the physical examination represents an important component and no one has been able to eliminate its subjectivity. Nyhus, Gilbert, Schumpelick, Harkins, Casten, Halverson and McVay, Lichtenstein, Bendavid, Stoppa, Alexandre, and Zollinger have developed groin hernia classification systems. The Nyhus system, which is detailed in Table 71.3, is the most widely used.

Clinical Diagnosis

Groin hernias present with a swelling that has a cough impulse. With indirect hernias, the swelling may extend down

TABLE 71.3 CLASSIFICATION**NYHUS CLASSIFICATION OF GROIN HERNIAS**

■ TYPE	■ DESCRIPTION
I	Indirect hernia Normal-size internal ring Typically in infants, children, small adults
II	Indirect hernia Dilated internal ring Posterior wall intact Inferior epigastric vessels not displaced Does not extend to the scrotum
III	Posterior wall defect
IIIA	Direct hernia Size not taken into account
IIIB	Indirect hernia Dilated internal ring encroaching on Hesselbach triangle (massive scrotal, sliding, or pantaloon type)
IIIC	Femoral hernia
IV	Recurrent hernia
IVA	Direct
IVB	Indirect
IVC	Femoral
IVD	Combined

into the scrotum. The swelling reduces when the patient lies down. Sometimes, the hernia does not reduce easily and the patient has to reduce it manually. Applying pressure over the midinguinal point (midway between the anterior superior iliac spine and the pubic tubercle and just above the inguinal ligament) with the fingertip will control an indirect hernia and prevent it from protruding when the patient strains. A direct hernia will not be controlled with this maneuver. Similarly, if the scrotum is invaginated with the index finger and the tip of the finger is placed through the external inguinal ring into the canal, and the patient is then asked to strain, an indirect hernia will push against the fingertip, whereas a direct hernia will push against the pulp of the finger. It should be noted that the accuracy of this clinical assessment is questioned by many authorities. A femoral hernia presents as a swelling below the inguinal ligament and just lateral to the pubic tubercle (Fig. 71.21).

Differential Diagnosis

The clinical presentation of a groin hernia, especially when large, is frequently obvious to the examiner. Smaller hernias and recurrent hernias can be confused with a number of different conditions that can be mistaken for a hernia (Table 71.4).

A hydrocele extending into the scrotum or an encysted hydrocele of the cord can involve the groin area. The distinguishing features are that the examining hand can get above a hydrocele but not above a hernia and that a hydrocele transilluminates very clearly. A varicocele does not transilluminate, has the characteristic feel of a “bag of worms,” and is more tubelike in conformation. Lesions of the testicle may sometimes mimic a hernia, particularly in inflammatory conditions, such as epididymo-orchitis. The distinguishing features are intense pain extending down into the scrotum. The testicle itself is enlarged and tender, as is the epididymis. On rectal examination,

the seminal vesicles are tender. This condition may be bilateral. Torsion of the testicle is distinguished by the fact that the testicle is absent from the scrotum and the swelling in the groin feels firm. A sonogram reveals a solid mass in the testicle, which has been pulled up because of the torsion. Testicular tumors, if large enough, may extend up to the groin area, but they have a solid feel and sonography can distinguish them.

Pseudohernia is a condition that occurs in patients with denervation of the abdominal wall musculature (e.g., after polio). The abdominal wall muscles bulge forward on straining and have the appearance of a hernia. An aneurysm of the femoral artery may present as a groin swelling but with an expansile impulse and sometimes a bruit. If thrombosis develops in the aneurysm, pulsation may be lost. In this instance, the aneurysm becomes tender. Femoral aneurysms move from side to side but not up and down. A saphena varix usually presents below the inguinal ligament and represents a varicosity of one of the branches of the long saphenous vein as it emerges from the hiatus. Like a hernia, the varix has a cough impulse and becomes more prominent when the patient is standing. Compression over the femoral hiatus obliterates this lesion. The varix is sometimes associated with varicose veins farther down the lower limb. The overlying skin has an associated bluish discoloration.

A lipoma within the spermatic cord is a very common condition and, from anatomic studies and surgical dissection, is now regarded as a hernia of the extraperitoneal fat.³⁹ If found at surgery, the lipoma is removed to avoid a persistent bulge in the inguinal region despite a successful hernia repair.

Enlargement of inguinal lymph nodes may also be mistaken for herniation. Inflammatory nodes are usually tender; metastatic lymphadenopathy is usually not tender. If inguinal lymph nodes are replaced by metastasis, a primary lesion should be looked for in the skin in any part of the lower limb. The perineum and anal canal should also be examined. Lymphadenopathy can also be caused by lymphoma, and groin nodes may be the only site. Lymphadenopathy characteristically appears as a well-circumscribed mass below the inguinal ligament that one can get above with the examining hand. Lymph nodes are solid on ultrasonography, and for this reason, it may be difficult to differentiate nodes from a femoral hernia containing omentum.

Surgical Indications. Most standard surgical texts continue to state that all inguinal hernias regardless of symptoms

should be repaired unless specific contraindications are present. This recommendation is based on the presumption that complications of incarceration, obstruction, and strangulation are greater threats than are the risks of operation. This concept is now being challenged for asymptomatic or minimally symptomatic patients. A recent randomized controlled trial comparing a strategy of watchful waiting to routine repair for male inguinal hernia patients with minimal symptoms revealed no difference in quality of life at 2 years and an acceptably low rate of hernia accident.⁴⁰ Given the possibility of the development of chronic postherniorrhaphy groin pain in up to 10% of patients undergoing repair, the notion that the presence of an inguinal hernia is an indication for repair can no longer be considered valid.

An alternative to surgical repair is a mechanical device known as a truss. It consists of a belt with a pad that is applied to the groin after spontaneous or manual reduction of a hernia and has been used for centuries. It serves to maintain reduction and possibly prevents enlargement of the hernia. There are insufficient studies to determine how effective trusses actually are and whether they are as good as surgery for the control of symptoms. Most patients find them cumbersome to use and difficult to keep clean. With prolonged usage, atrophy of the spermatic cord has been reported and eventual surgical repair is made more difficult due to fibrosis of the tissues. However, some patients do achieve symptomatic relief.

Treatment

- 5 Four developments in the latter half of the 20th century significantly decreased morbidity and favorably influenced the recurrence rate to the currently accepted level of less than 2%: (a) the routine use of prosthetic materials, (b) the widespread acceptance of the “tension-free” concept, (c) the realization that the preperitoneal space can be used for hernia repair, and (d) therapeutic laparoscopy. These concepts are discussed in this section; the treatment strategies are divided between an open approach in the conventional anterior space and a preperitoneal approach, either open or laparoscopic.

Open Approach. The simplest Nyhus type I indirect inguinal hernias, which include most inguinal hernias in children, are adequately treated by obliteration of the congenital patent processus vaginalis alone. Since the inguinal floor is otherwise normal, reconstruction is not required. Classically, the hernia sac is dissected from the cord structures, ligated, and removed at its origin at the internal ring, so-called high ligation of the sac, thus the term *herniotomy*. The skin incision starts at the pubic tubercle and is extended laterally. The external oblique aponeurosis is opened in the line of its fibers through the external ring and the lower leaf is freed from the spermatic cord. The spermatic cord is freed from the floor of the inguinal canal and the pubic tubercle. Mobilization of the cord structures is completed by means of blunt dissection, and a Penrose drain is placed around them so that they can be retracted during the procedure.

The genital branch of the genitofemoral nerve and the spermatic vessels are included with the cord. The ilioinguinal and iliohypogastric nerves are usually preserved. The cremasteric fibers are separated, and the hernia sac is dissected from the cord structures to a point proximal to the internal ring. Ligation can be performed at this point (high ligation), followed by division of the neck of the sac. Prior to this the sac can be opened to allow a digital examination of the abdominal cavity and femoral ring. Alternatively, the sac may be simply inverted. The proponents of not opening the sac feel that with this method the patient experiences less pain because the highly innervated peritoneum has not been violated.

The terms *herniorrhaphy* or *hernioplasty* are used when a procedure to reconstruct the inguinal floor is added. For indirect

hernias the sac is first dealt with in an identical manner as for a herniotomy. The only exception is large indirect inguinal scrotal hernias where complete removal of the sac might result in too high of an incidence of cord and testicular complications because of the extensive dissection required to completely separate them from the cord. Most authorities believe that these large sacs are best transected at the midpoint of the canal, and the distal sac is left in situ. Direct hernia sacs are almost never removed but instead are dissected from surrounding structures and reduced into the preperitoneal space. Dividing the transversalis fascia circumferentially at the neck (base) of the sac will aid in this reduction in some cases. The defect may be closed primarily at this point to maintain the reduction while a formal repair is being performed. The latter is considered a matter of convenience and adds nothing to the strength of the final outcome. The area of weakness in the posterior wall is then reinforced with the patient's own tissues.

The next step is to reconstruct the inguinal floor. There are two ways to do this. The first is a tissue repair, so named because only the patient's native tissue is used without foreign prosthetic material. The second is the tension-free repair (TFR). This implies the use of a prosthesis to repair the weakened inguinal floor, eliminating the need to reapproximate tissues that were not in apposition naturally. Edoardo Bassini (1844–1924) is considered the father of modern inguinal hernia surgery because in the latter part of the 19th century he introduced the first tissue repair based on solid anatomic principles, which became the “gold standard” for inguinal hernia repair for most of the 20th century. His scientific approach led to the development of several distinct steps essential for the procedure (Table 71.5). Before Bassini's achievements, elective herniorrhaphy was almost never recommended, because the results were so bad.

Today, there are at least 70 named tissue repairs described in the literature.⁴¹ Most are relatively minor modifications of the Bassini, Shouldice, and McVay repairs and therefore, for the purposes of this chapter, only these will be presented. In the Bassini repair, the transversus abdominis aponeurosis together with the transversalis fascia is sutured to the shelving edge of the inguinal ligament with nonabsorbable interrupted sutures (Fig. 71.23). In the Shouldice repair, the transversalis fascia is divided from the internal ring to the pubic tubercle. The musculofascial elements laterally are then sutured to different levels of the inferior flap of the external oblique aponeurosis with four rows of running sutures (Fig. 71.24). Although the suture material originally used for this repair was stainless steel wire, other nonabsorbable materials, such as Prolene, are now used. The McVay repair (Fig. 71.25) addresses both inguinal and femoral hernias. The central attenuated portion of the inguinal floor is excised. The Cooper ligament must be clearly identified. The inguinal floor is then repaired by approximating the transversus abdominis aponeurosis and transversalis fascia to the Cooper ligament between the pubic tubercle and the femoral vein. A so-called transition stitch is then necessary between the transversalis fascia, Cooper ligament, and inguinal ligament to

TABLE 71.5

TREATMENT

ESSENTIAL STEPS FOR THE INGUINAL HERNIA REPAIR

1. Complete division of the external oblique aponeurosis and the transversalis fascia
2. Differentiation between indirect and direct defects
3. Isolation of the spermatic cord
4. Ligation and removal of the sac at the deep inguinal ring flush with the peritoneum
5. Oblique reconstruction of the inguinal canal with an anterior and posterior wall and an internal and external ring

FIGURE 71.23. Bassini repair.

FIGURE 71.24. Shouldice repair.

FIGURE 71.25. McVay (Cooper ligament) repair.

bring the repair above the femoral vessels. The repair is then continued laterally along the inguinal ligament.

A relaxing incision is necessary for repairs of large indirect hernias and whenever the McVay repair is used. Failure to make a relaxing incision has been implicated in a greater incidence of recurrence. The relaxing incision is made in the anterior rectus sheath in a vertical direction and is extended 3 to 4 cm above the pubis to a level opposite the internal ring (Fig. 71.25). The resulting defect in the sheath is protected posteriorly by the body of the rectus muscle, which prevents herniation at that site.

The most popular TFR is the Lichtenstein operation (Fig. 71.26).⁴² The initial dissection is identical to the tissue repairs described. Once the sac has been dealt with, a 15 × 11-cm sheet of polypropylene mesh is used, the medial end of which is

rounded to the shape of the medial corner of the inguinal canal. This medial end is sutured to the anterior rectus sheath 2 cm medial to the pubic tubercle. In deference to nerve entrapment, most surgeons now use an absorbable suture, something considered heresy in the past. The same suture is then continued laterally in a running locking fashion securing the inferior edge of the prosthesis to either side of the pubic tubercle and the shelving edge of the inguinal ligament. The periosteum of the bone is avoided to prevent osteitis pubis. The suture is continued to attach the lower edge of the prosthesis to the shelving edge of the inguinal ligament up to a point just lateral to the internal ring. If a femoral hernia is present, the posterior surface of the mesh is sutured to the Cooper ligament after the inferior edge has been attached to the inguinal ligament. This closes the femoral canal. A slit is cut in the lateral end of the

FIGURE 71.26. The Lichtenstein hernioplasty, showing placement of the mesh.

mesh to produce a narrow (one-third width) tail below and a wider (two-thirds width) tail above. The spermatic cord is positioned between the two tails. The wider tail is placed over the narrow one and a so-called shutter valve stitch placed just lateral to the cord including the inferior surface of the superior tail, the inferior surface of the inferior tail, and the inguinal ligament. The tails are then tucked under the external oblique aponeurosis to the level of the anterior superior iliac spine. The external oblique aponeurosis is closed to re-create the external ring. The wound is closed in layers.

A popular modification of the Lichtenstein operation has been termed the plug-and-patch repair. As the name implies, a plug usually constructed from polypropylene is inserted in the defect and secured with interrupted sutures to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia). The patch is then placed over the plug to cover the inguinal floor as in the Lichtenstein. One might argue that this operation is nothing more than a Lichtenstein on top of a plug, and in fact the term “plugstenstein” has been used to describe it. However, the difference with a plug-and-patch repair is that only one or two sutures—or, sometimes, no sutures—are used to secure the flat prosthesis to the underlying inguinal floor. This results in an operation that is fast and very easy to teach.

Femoral hernias can be repaired from a lower approach, in which a vertical incision is made over the femoral triangle in the upper thigh. The hernia is approached from below the inguinal ligament and reduced, and then the defect is closed by suturing the inguinal ligament to the Cooper ligament from below. An alternative is to insert a rolled plug of mesh into the defect and suture the periphery to the inguinal ligament and Cooper ligament.⁴³ The repair can also be carried out from above via an inguinal approach, as in the McVay repair. The posterior floor of the inguinal canal is dissected out, and the Cooper ligament is repaired after the hernia has been reduced. A third type of femoral hernia repair is the preperitoneal repair. Access to the preperitoneal space is gained through an abdominal incision or laparoscopy. Femoral hernias are more common in women and often present with an acute episode of incarceration, intestinal obstruction, or strangulation, so that emergency surgery is necessary. It can be difficult to reduce the hernia at surgery, and it is not uncommon to have to divide the inguinal ligament to obtain greater freedom to perform this reduction.

Inguinal herniorrhaphy can be performed under local anesthesia. Indeed, throughout the world, local anesthesia has

become the standard method of anesthesia for this operation. Its greatest advantage is the virtual elimination of urinary retention when compared to regional or general anesthesia.⁴⁴ Hernias in high-risk patients can be safely repaired under local anesthesia.

Preperitoneal Approach. The preperitoneal space is situated between the transversalis fascia and the peritoneum. The final common denominator in all groin hernias is failure of the transversalis fascia to retain the intra-abdominal contents. Repairs performed in this space make the distinction between direct, indirect, and femoral irrelevant because the repair is accomplished behind the defective transversalis fascia, addressing the entire myoepectineal orifice.

For a conventional, open operation, the preperitoneal space can be entered via a lower midline incision or a transverse incision placed slightly higher than usual. The rectus muscle is retracted medially and the preperitoneal space entered. A large prosthesis is used that extends far beyond the margins of the myoepectineal orifice and envelops the visceral sac. The mesh is held in place by intra-abdominal pressure, which pushes outward toward the undersurface of the transversalis fascia. Because the incision for a preperitoneal hernia repair is away from the groin area and directly accesses the preperitoneal space, dissection of the inguinal canal, spermatic cord, or sensory nerves of the groin is not performed. The complications involving these structures that occur with other hernia repairs are very rare with the preperitoneal repair. If the hernial sac is large, it is amputated or inverted beneath a pursestring suture to smooth the external surface of the visceral sac. The distal peritoneal sac is left in place, undissected, and attached to the cord. With a sliding indirect hernia, the sac is easily dissected away from the cord. Proponents of this technique feel that polyester is better suited than other prostheses because of its pliability. For a bilateral repair, one large chevron-shaped mesh can be used for both sides.

Several newer, less invasive preperitoneal techniques have been developed to place a mesh in the preperitoneal space. For example, in the Kugel procedure, a small incision is made over the deep inguinal ring and the preperitoneal space is developed bluntly followed by the use of a prosthesis with an incorporated reinforcing ring. This ring can be deformed to allow the prosthesis to be introduced into the preperitoneal space and then the ring causes it to spring back to its original shape, providing wide overlap of the myoepectineal orifice.⁴⁵ The procedure works well in experienced hands but because it is partially

blind, considerable training is required. Another approach is to take advantage of both the preperitoneal space and the conventional anterior space using a bilayered prosthesis in which a cylinder of prosthetic material connects the two layers through the hernia defect or the internal ring.⁴⁶

6 Laparoscopic Approach. The terminology to describe a laparoscopic inguinal herniorrhaphy can be confusing. A laparoscopic preperitoneal hernia repair, in which a laparoscopy is performed and the preperitoneal space is entered with a second incision in the peritoneum, is called a *transabdominal preperitoneal repair*, or TAPP repair. An inguinal hernia repair in which prosthetic material is placed intraperitoneally over the defect under laparoscopic guidance is referred to as an *intraperitoneal onlay mesh repair*, or IPOM repair. The third general type of laparoscopic approach is the *totally extraperitoneal laparoscopic repair*, or TEP repair. Laparoscopy, by definition, implies that the peritoneal cavity has been entered. To refer to this technique as *extraperitoneal* therefore represents a contradiction in terms. However, because a laparoscope and related instruments are used, it is fitting to discuss the extraperitoneal approach along with the other laparoscopic inguinal herniorrhaphies.

The TAPP and the TEP laparoscopic inguinal herniorrhaphies are the most popular. Both are modeled after the conventional preperitoneal operations. The major difference is that the preperitoneal space is entered through three trocar sites rather than through a large conventional incision. The ensuing radical dissection of the preperitoneal space with placement of a large prosthesis is similar to the conventional preperitoneal operation.

Laparoscopic Versus Conventional Herniorrhaphy. Randomized controlled trials as well as a meta-analysis of pooled data from these trials have shown that on average, patients undergoing laparoscopic herniorrhaphy have less pain initially than open, tension-free herniorrhaphy and return to normal activities sooner.⁴⁷ The difference is even greater when the comparison is made to nonprosthetic repairs. However, the potential advantages of laparoscopic herniorrhaphy must be interpreted in light of the disadvantages, which include complications related to the laparoscopy such as bowel perforation or major vascular injury, potential adhesive complications at sites where the peritoneum has been breached or prosthetic material has been placed, the need for a general anesthetic, and increased cost because of the expensive equipment. On the other hand, the conventional operation can be performed under local anesthesia on an outpatient basis, with minimal risk of intra-abdominal injury, and the cost is less.

Patient Selection. Perhaps the most important element in patient selection has nothing to do with the patient but has to do with the surgeon's skill. Laparoscopic inguinal herniorrhaphy is more challenging technically than a conventional open tension-free procedure. Assuming equivalence for recurrence and complication rates between laparoscopic inguinal herniorrhaphy and a tension-free herniorrhaphy for a given surgeon, all adult patients with inguinal hernias who are candidates for general anesthesia can be considered candidates for laparoscopic inguinal hernia repair. Certain hernia types, such as those that are recurrent, bilateral, or otherwise complicated, are particularly suited for the laparoscopic approach.⁴⁸ In addition, women may be better served with a laparoscopic operation because the femoral space is addressed, which should eliminate the excessive incidence of femoral recurrence observed with conventional operations such as the Lichtenstein.³⁷

Contraindications include intra-abdominal infection and coagulopathy. Relative contraindications include intra-abdominal adhesions from previous surgery, ascites, or previous retropubic space surgery, because of the increased risk for bladder injury. Severe underlying medical illness is also a relative contraindication because of the added risk of general anesthe-

sia. These patients are better suited for a conventional operation under local anesthesia. An incarcerated sliding scrotal hernia is a relative contraindication, especially when it involves the sigmoid colon, because of the high risk for perforation during the dissection.

Operative Techniques

Transabdominal Preperitoneal Repair. The procedure is begun with a thorough diagnostic laparoscopy to rule out unrelated pathology and carefully inspect both myoepectineal orifices. Two additional cannulae are placed just lateral to the rectus sheath on either side of the umbilicus (Fig. 71.27). For a unilateral hernia, a transverse incision is begun at the lateral side of the medial umbilical ligament and extended to open its lateral leaf to the anterior superior iliac spine. If the medial umbilical ligament appears to compromise exposure, it can be divided. Electrocautery is used to minimize bleeding from the remnants of the embryologic umbilical artery. A radical dissection of the preperitoneal space is then performed with mostly blunt dissection and generous use of electrocautery, as bleeding in this area is particularly troublesome if it interferes with illumination. The ipsilateral and contralateral pubic tubercles, inferior epigastric vessels, Cooper ligament, and iliopubic tract are identified (Fig. 71.28). The cord structures are mobilized, and the peritoneal flap is dissected several centimeters proximal to the bifurcation of the vas deferens and the internal spermatic vessels. Recurrences have been attributed to inadequate mobilization of the peritoneal flap, which does not allow the prosthesis to lie flat in this area. If small, an indirect sac is mobilized away from the cord structures and reduced. If large, the sac is divided at a convenient point distal to the internal ring and only the proximal portion is mobilized. A direct sac readily reduces during the preperitoneal dissection. An easily visible layer of fatty tissue separates the thinned out transversalis fascia lining the defect and the peritoneum.

A large piece of polypropylene mesh (at least 14 × 11 cm) is placed in the preperitoneal space to cover the contralateral pubic tubercle medially and extending onto the anterior abdominal wall superiorly at least 2 cm above the hernia defect, to the anterior superior iliac spine laterally, and over the Cooper ligament inferiorly. Most surgeons prefer to fasten the prosthesis with staples, tacks, or glue, but there is increasing evidence that fixation is not necessary when a large prosthesis is used that widely overlaps the entire myoepectineal orifice. Staples or tacks are never placed below the iliopubic tract when lateral to the internal spermatic vessel because of the danger of damage to the important nerves in this area. The last step is to cover the prosthesis by closing the peritoneum with sutures, tacks, staples, or glue. The goal is to isolate the prosthesis from the abdominal viscera rather than to always achieve precise approximation of the peritoneal edges. This is because gaps can form if the peritoneum is closed under tension allowing bowel to migrate into the preperitoneal space. A better option is to secure the inferior peritoneal flap to the transversalis fascia above the prosthesis and leave the superior flap alone.

For bilateral inguinal hernias, the same peritoneal incision and preperitoneal dissections are used. The symphysis pubis is completely exposed so that both preperitoneal dissections communicate with each other. This exposure allows the placement of one large prosthesis (at least 25 × 8 cm) that essentially covers the entire lower pelvis. By not incising the peritoneum between the two medial umbilical ligaments, one avoids the theoretical complication of dividing a patent urachus.

Totally Extraperitoneal Laparoscopic Repair. An incision is made at the umbilicus, as if one were planning to perform open laparoscopy. The rectus sheath is opened on one side and the rectus muscle is retracted laterally. Blunt dissection is then begun in the space between the rectus muscle and the posterior rectus sheath. Once the space is large enough, two additional

FIGURE 71.27. Typical operative setup and cannula site selection for a transabdominal preperitoneal (TAPP) laparoscopic inguinal herniorrhaphy.

cannulae are placed in the midline, one approximately 5 cm above the symphysis pubis and the other midway between the umbilicus and the symphysis pubis. The dissection of the preperitoneal space is completed under direct vision. The rest of the operation is identical to the TAPP procedure described previously except that peritoneal closure is not necessary. Popular alternatives are to use a water- or air-filled balloon dis-

sector to perform the preperitoneal dissection and to place the two accessory cannulae on either side of the umbilicus, as in the TAPP procedure, instead of in the midline.

The presumed advantages of the TEP procedure are that the inherent complications of entering the peritoneal cavity, such as intra-abdominal organ injury or postoperative bowel obstruction secondary to adhesions or trocar site herniation,

FIGURE 71.28. Important structures that must be identified after a preperitoneal dissection: inferior epigastric vessels, Cooper ligament, spermatic vessels, vas deferens, iliopubic tract, genitofemoral nerve, femoral nerve, lateral femoral cutaneous nerve, ilioinguinal nerve, iliacus muscle, and psoas major muscle.

are avoided. However, the operative space is limited, and considerable experience is required to become familiar with the anatomy from this perspective. In addition, it is not yet clear whether inadvertent breaches in the peritoneal cavity that are difficult to visualize because of the direction of the optics might negate the potential benefits of this approach.

Intraperitoneal Onlay Mesh Repair. The TAPP and the TEP herniorrhaphies are better considered minimal access procedures rather than minimally invasive because of the extensive dissection required in the preperitoneal space. The IPOM procedure was developed to be a truly minimally invasive operation. By placing the prosthesis one layer deep to the preperitoneal space directly onto the peritoneum, one can eliminate the need for a radical preperitoneal dissection. Initial laparoscopy and accessory cannula placement are the same as in the TAPP procedure. A large piece of prosthetic material is introduced into the peritoneal cavity and secured in place with staples, tacks, or sutures. An attempt is made to use the same landmarks described previously for the TAPP procedure. The main concern is development of the complications of intraperitoneal placement of a prosthesis in contact with intra-abdominal organs. The procedure is regaining some popularity because of the development of the adhesion barrier prosthetics for ventral hernia (see later).

SPORTS HERNIA

The term *sports hernia* is confusing because, by definition, the patients do not actually have a hernia but rather a weakness of the posterior inguinal floor. The condition has received considerable attention in the lay press because of its prevalence in high-profile athletes involved in sports who require rapid changes in direction of the hip area such as soccer, football, basketball, track and field, tennis, and hockey. The first step in approaching

FIGURE 71.29. Complicated arrangement of muscle pulling in different directions that attach to the pubic bone.

these patients is to make sure one is not dealing with a cause outside of the groin with referred pain, such as lumbosacral radiculopathic pain, prostatitis, hip disease, and a gastrointestinal cause. The differential diagnosis is listed in Table 71.6. Alteration in the complex balance that must be maintained between the lower abdominal muscles and the leg adductor muscles and tendons, all revolving around the area of the pubic bone, is the final common denominator for many of the conditions that cause groin pain in up to 5% of athletes (Fig. 71.29).⁴⁹

Some authorities prefer to refer to this condition as “athletic pubalgia,” as this conveys the concept that the physical examination is inconclusive and the cause of groin pain is unclear. The most important differential diagnoses in addition to an occult groin hernia include adductor tenoperiostitis, osteitis pubis, symphysis syndrome, Gilmore groin (groin disruption), iliopsoas bursitis, stress fractures, or avulsion fractures. Cross-sectional imaging (CT or magnetic resonance imaging [MRI]) is the most useful diagnostic modality in the absence of a highly experienced ultrasonographer.⁵⁰ MRI shows particular promise for the future with the development of fast imaging scanners that will allow dynamic imaging (i.e., performed during straining) with or without the addition of intraperitoneal contrast agents.

The treatment is conservative with forced inactivity, elastic immobilization bandages, ice/massage, nonsteroidal anti-inflammatory analgesics, and occasional steroids (systemic and/or local). Surgery is a last resort. Although lacking clear-cut anatomic justification, a mesh hernia repair similar to either an anterior Lichtenstein or a TEP laparoscopic operation is the most popular procedure, sometimes combined with a variety of muscle reattachment procedures and tenotomies. The best results are obtained with a multidisciplinary approach including a surgeon, an orthopedist, a physical therapist, and a sports

the natural history is different. Results of operations vary depending on the specific hernia. Table 71.7 uses the common terminology familiar to all surgeons for classifying abdominal wall hernias. Table 71.8 is a classification system published by Zollinger that expands upon Table 71.7 by further subdividing ventral hernias based on etiology.⁵¹

UMBILICAL AND PERIUMBILICAL HERNIAS

Umbilical and periumbilical hernias are usually congenital, caused by arrest of the normal spontaneous closure of the umbilical ring through which umbilical blood vessels pass in the developing fetus, which results in a defect in the fascia covered by skin. In infants, the fascial defect varies in size but is most commonly 1 to 2 cm. A large proportion of pediatric umbilical hernias heal spontaneously, and 80% of them close by the time the patient is 2 years old. This is the only abdominal wall defect genetically programmed to close. Persistent umbilical hernias require surgery. In older patients, the onset is usually sudden and the defect is relatively small. There are several syndromes associated with umbilical hernias such as mucopolysaccharide storage diseases, Beckwith-Wiedemann syndrome, and Down syndrome. Predisposing factors for the development of umbilical hernias in adults are multiple pregnancies, obesity, cirrhosis with ascites, and large abdominal tumors, all of which cause an increase in intra-abdominal pressure.⁵² The differential diagnosis includes the varicosities that extend radially from the umbilicus in persons with portal hypertension, the so-called caput medusae (Fig. 71.30). The varicosities have a bluish discoloration and fill when the patient is straining. A metastatic deposit of intra-abdominal cancer at the umbilicus may mimic umbilical herniation. Cancer cells reach this area via lymphatics in the falciform ligament. Metastasis presents as a hard nodule, and biopsy is diagnostic. Other periumbilical masses that can be confused with an umbilical

FIGURE 71.30. Caput medusae. Large periumbilical collaterals in a patient with portal hypertension.

hernia include umbilical granulomas, omphalomesenteric duct remnant cysts, and urachal cysts.

The management of umbilical hernias is nonoperative in children up to the age of 2 or 3 years because spontaneous closure is the rule. In those who require surgery, adults or children, the repair depends on the size of the hernia. An infraumbilical semilunar incision is made and the hernia identified. There may or may not be a true peritoneal sac, as smaller hernias usually consist of preperitoneal fat only. If a sac is present, it can be opened and the contents reduced into the abdomen. Alternatively, the hernia can be dissected circumferentially to the fascial opening and reduced without entering the peritoneal cavity. The dissection can be continued beneath the fascias creating a preperitoneal space for the placement of a prosthesis if needed. Several techniques can be used to close the fascial defect. In 1901, James Mayo described the classic overlapping, vest-over-pants (double-breasting or waistcoat) technique, which bears the name of his clinic, in which the upper edge of the linea alba overlaps the lower edge (Fig. 71.31).⁵³ The operation is losing popularity now because it is generally not consistent with the tension-free concept popular in hernia surgery today.⁵⁴ It requires more dissection than other procedures to create the flaps and is therefore more painful. Simple suture herniorrhaphy is the easiest procedure but has the highest recurrence rate and therefore should be used only for small defects. For larger hernias, particularly in adults, the preperitoneal space can be exploited by bluntly dissecting the peritoneum from the undersurface of the posterior rectus sheath for enough distance to be able to place an appropriate prosthesis. If the peritoneum is not entered, a mesh prosthesis is preferred, which is placed in the preperitoneal space and then the fascial edges closed if the defect is small enough. Otherwise, a bridging technique can be used with the fascial edges sewn to the underlying mesh. If the peritoneal cavity is entered, then a composite prosthesis (e.g., ePTFE + polypropylene) or a mesh prosthesis with an adhesion barrier (see prosthetic materials section) can be placed intraperi-

toneally with the adhesion barrier facing the viscera. A laparoscopic approach for umbilical hernias is a good option for recurrent hernias or hernias with defects larger than 3 cm and, in retrospective reviews, has been shown to decrease operative times and result in faster recovery to normal activities.⁵² The technical details are similar to a laparoscopic incisional hernia repair (see incisional hernia section).

EPIGASTRIC HERNIAS

Epigastric hernias occur through a defect in the linea alba. In the majority of patients, only a single decussation of the fibers of the linea alba is present rather than the usual triple decussation (Fig. 71.7). The incidence of epigastric herniation reported varies from less than 1% to as high as 5%. Epigastric hernias are two to three times more common in men than in women. About 50% of them are asymptomatic. Most are less than 1 cm and contain only incarcerated preperitoneal fat without a peritoneal sac. For this reason, epigastric hernias commonly cannot be visualized with laparoscopy. Patients complain of a painful nodule in the upper midline. Repair by reduction of the preperitoneal fat and simple closure of the defect is curative. These hernias are prone to recur, with rates as high as 10%, which has led many surgeons to routinely include a prosthetic underlay just as in umbilical or incisional hernias.

Left untreated, an epigastric hernia can become large enough for a peritoneal sac to form, into which the intra-abdominal contents can protrude. The sac is usually wide, and serious complications are not common. Twenty percent are multiple, and this needs to be ascertained prior to operation if all the defects are to be addressed, because after anesthesia induction, they can be difficult to identify.

In *diastasis recti*, the two rectus muscles are separated widely. The area of the linea alba is stretched and protrudes like a fin. The condition almost never produces complications and therefore surgical correction is not routinely recommended. However, many patients find the defect unsightly and request treatment. They should be cautioned that many insurance companies consider this a cosmetic defect and will not reimburse. Surgery involves removal of a strip of the weakened linea alba and reapproximation. An alternative is a mesh repair done laparoscopically.

INCISIONAL HERNIAS

Incisional hernias occur as a complication of prior surgery. These hernias can follow any type of abdominal surgery, regardless of the type of incision. More than 2 million laparotomies are performed yearly in the United States, and the reported incidence of incisional hernia varies between 2% and 11%.⁵⁵ The highest incidence is with midline incisions (10.5%) and transverse incisions (7.5%), but hernias are well documented following paramedian incisions as well (2.5%).⁵⁶ Read and Yoder in a retrospective review found that 17% of incisional hernias are incarcerated or strangulated at presentation.⁵⁷ Most of the published literature on treatment options addresses midline defects. The management of non-midline incisional hernias (i.e., subcostal, transverse, or gridiron incisions) to some extent must be extrapolated.⁵⁸ The consequences of unrepaired enlarging symptomatic hernias include loss of abdominal domain; significant biomechanical alterations that affect posture; compromise of activities of daily living, including lifting and straining; and poor cosmetics.

The cumulative incidence of incisional hernias is linear, as they can present after considerable delay following the index operation. Poor surgical technique, rough handling of tissues, use of rapidly degraded absorbable suture materials, closure of

FIGURE 71.31. Mayo repair of an umbilical hernia. **A:** Diagram of longitudinal section through the hernia. **B:** Subumbilical "smile" incision. The hernial sac is excised. **C:** Waistcoat type of closure.

FIGURE 71.32. Component separation technique.

the abdomen under tension, and infection of the wound are technical causes of incisional hernias. Morbid obesity, cigarette smoking, pulmonary disease, debilitation from cancer, chemotherapy, the use of steroids, hypoalbuminemia, and other preexisting comorbid conditions are patient factors that have been incriminated. Patients with an aortic aneurysm or a proven defect in collagen metabolism also exhibit an increased incidence of incisional hernias.⁵⁹

At least some ventral hernias can be prevented by proper abdominal closure after any laparotomy. Sutures should be placed 1 cm away from the edge and 1 cm apart from each other. The length of the suture should be four times the length of the wound to avoid excessive tension.⁶⁰ It is now generally agreed that monofilament suture material used in a continuous running fashion is best. Studies have shown that nonabsorbable sutures result in a lower incidence of incisional herniation but at the cost of increased wound pain and chronic suture sinuses when they become infected.⁶¹ These suture sinuses tend to be multiple and take years to eradicate by probing the sinus tracks and removing deep sutures. The development of better monofilament absorbable sutures has caused most surgeons to avoid nonabsorbable closure material.

Treatment

7 Nonprosthetic Repairs. Traditionally, the repair of an incisional hernia depended on the size of the hernia. If the defect was solitary and 3 cm or less, primary closure with nonabsorbable suture material was recommended. This concept is now questioned after the publication of a landmark prospective randomized trial by Luijendijk et al. from The Netherlands in the year 2000 and updated in 2004 comparing a prosthetic repair versus primary suture.^{62,63} These investigators found a 50% reduction in the recurrence rate when a prosthesis was used, and this even applied to small hernias. For this reason, a simple, nonprosthetic technique should be reserved for only the smallest hernias in patients without risk factors for further recurrence.

A more complex nonprosthetic repair is the component separation technique popularized in the early 1990s by Ramirez et al.⁶⁴ The skin and subcutaneous fat are dissected free from the anterior sheath of the rectus abdominis muscle and the aponeurosis of the external oblique muscle. The aponeurosis of the external oblique muscle is transected longitudinally just lateral to the lateral side of the rectus sheath (Fig. 71.32). It is important to extend the incision onto the chest wall at least 5 to 7 cm cranial to the costal margin. The external oblique muscle is separated from the internal oblique muscle, as far laterally as possible. This step is safe because the neurovascular bundle (comprising the intercostal nerves and vessels) lies deep to the internal oblique muscle. The result is that the internal oblique

muscle and the rectus abdominis slide medially. When necessary, 2 to 4 cm of additional length can be gained by separating the posterior rectus sheath from the rectus abdominal muscle. Care must be taken not to damage the neurovascular bundle that runs between the internal oblique and transverses abdominis muscle to enter the rectus sheath posterolaterally. The technique can also be used as an adjuvant to the prosthetic repairs described next, but the extensive flap dissection between the two procedures results in an increased incidence of abdominal wall devascularization. A technique that employs a balloon dissector and laparoscopic instruments to lessen the degree of abdominal dissection has been described, but it remains to be seen if it is effective (Fig. 71.32).⁶⁵

Prosthetic Repairs. The concept of prosthetic use is not new as it was proposed by Usher et al. in 1958 for hernia repair using the polypropylene mesh Marlex.⁶⁶ Over the ensuing years, lessons have been learned: (a) the use of absorbable mesh leads to a high relapse rate, (b) repetition of a previously inadequate technique frequently fails, (c) a simple inlay technique that bridges the defect has a high failure rate, (d) reinforcement of the entire scar is advisable irrespective of operative findings, and (e) the success of a mesh repair depends on the extent of overlap or underlap.⁶⁷

Numerous techniques for prosthetic incisional hernia repair have been described, which is not surprising since there are so many variables. For example, there are five potential spaces to place a prosthesis (Figs. 71.3 and 71.33).

FIGURE 71.33. Potential spaces in the abdominal wall to place prosthetic material: onlay or on top of the anterior abdominal fascia; under the anterior fascia but in front of the muscle (if the mesh bridges that space, it would be an inlay technique); retrorectus space or the underlay technique below the muscle but above the posterior fascia; preperitoneal (important when below the arcuate line); intraperitoneal.

Because of the number of different repairs, it is not practical to describe each one in detail. However, most of them represent a variation of one of the general classes described.

Onlay Prosthetic Technique. The basis of this procedure is to place a prosthesis over any of a wide variety of simple repairs. Although it has some proponents, many surgeons feel that this technique offers little advantage over the simple repair that the prosthesis overlies.⁶⁸

Prosthetic Bridging Technique. A prosthetic bridging repair became popular in the 1990s in keeping with the tension-free concept for inguinal herniorrhaphy. The basic principle underlying this technique is that for a prosthetic repair to be effective, the defect should be bridged. Although this repair is theoretically attractive, it has not been nearly as successful for incisional hernias as for inguinal hernias. The recurrence rate is especially high in obese patients. It is not recommended.

Combined Fascia and Mesh Closure. This group of repairs combines features of the component separation technique with the tension-free concept. By incising the anterior fascia and rotating the medial edge toward the midline in continuity with the posterior fascia, the posterior fascia is effectively lengthened (Fig. 71.34). The posterior fascia is closed primarily, but the anterior fascia is bridged with a prosthesis.

Sublay Prosthetic Technique. The sublay prosthetic repair, sometimes referred to as the retromuscular approach, is characterized by the placement of a large prosthesis in the space between the abdominal muscles and the peritoneum (Fig. 71.17). It was popularized by Velamanta, Stoppa, and Wantz and is particularly suitable for large and multiply

FIGURE 71.34. 1, Hernia defect with bulging sac. 2, Anterior fascia is incised longitudinally on either side of the defect. 3, The anterior fascia is then rotated medially, in effect lengthening the posterior sheath to allow primary closure, isolating the abdominal contents from the anterior fascia. 4, Prosthetic material is used to bridge the anterior fascia.

FIGURE 71.35. Perforating blood vessels supplying the rectus muscle.

recurrent hernias when most of the abdominal wall must be reconstructed.^{69–71} It is considered the most effective conventional incisional hernia repair and therefore the one against which other procedures must be measured. Its major disadvantage is its need for wide undermining of the abdominal layers with the potential risk of devascularization of the abdominal wall or the creation of a large seroma, which later leads to infection. Suction drains are used by most surgeons, although the literature does not unequivocally support their use.⁷²

The procedure is begun by excising the previous scar and dissecting the peritoneal sac of the hernia to the level of the fascia. Occasionally, the sac does not have to be opened and the procedure can be performed totally extraperitoneal. More commonly, the sac is thin and easily disrupted, making entrance into the peritoneal cavity inevitable. The posterior rectus sheath is opened on each edge of the hernia defect and dissected away from the undersurface of the recti to the lateral edge of the rectus sheath, with care being taken to prevent damage to the perforating blood vessels at the lateral side of the sheath (Fig. 71.35). The posterior rectus sheaths are then approximated to each other primarily (unless the peritoneum has not been opened). During this part of the procedure, flaps must be created by dissecting the skin and subcutaneous tissue off of the underlying fascia laterally until enough tension is relieved to allow primary closure of the anterior rectus sheath. It is sometimes necessary to add component separation to further decrease the tension. A large mesh prosthesis (combined with ePTFE or an adhesion barrier if the approximation of the posterior rectus sheath is inadequate) is then placed in this space outside the repaired posterior sheath but beneath the recti. The mesh is secured in this position with several sutures directly to the posterior rectus sheath. An alternative is to use a suture passer to pass the two tails of a suture placed on the lateral side of a prosthesis through the lateral edge of the rectus sheath through separate fascia openings. The suture is then tied in the subcutaneous tissue resulting in a secure anchoring of the prosthesis in the abdominal wall. If the subcutaneous tissue dissection from the anterior rectus sheath has not been too extensive, the sutures cannot be retrieved in the subcutaneous tissue and therefore the suture passer is pushed through the entire thickness of the subcutaneous tissue and then through a small stab incision in the skin. The suture is tied and the knot allowed to retract back into the subcutaneous tissue and the skin is approximated over it. The procedure is completed by reapproximating the anterior rectus sheaths, thus bringing the rectus muscles back to their normal configuration. The best long-term results are obtained when the anterior fascia can be closed bringing the muscles back together because of an improvement in abdominal wall mechanics. However, it is sometimes impossible

FIGURE 71.36. Fixation of prosthesis to the peritoneal surface of the abdominal wall with use of a suture passer. Step 1: The suture passer device with a heavy nonabsorbable suture is passed through a 3-mm stab incision in the skin at an oblique angle. The device and suture traverse the entire abdominal wall and then the prosthesis. Once the peritoneal cavity is entered, the suture is released and the passer is withdrawn back into the subcutaneous tissue. Step 2: The device is redirected at a different angle through the abdominal wall and prosthesis and the suture is grasped. Step 3: The suture is pulled out of the abdominal cavity so that the two free ends are extracorporeal. Step 4: The suture is tied with the knot resting on the fascia. The skin is then closed.

to achieve this and the gap must be bridged with a prosthesis (Fig. 71.36).

Laparoscopic Ventral Hernia Repair. This operation was developed in the 1990s as a natural extension as surgeons became trained in the laparoscopic method for many commonly performed abdominal procedures. Although smaller hernia defects can be closed primarily, its greatest value is that the “gold standard” sublay technique can be replicated by the intra-abdominal placement of a submuscular prosthesis, eliminating the need for the extensive abdominal wall dissection implicit in the conventional operation. ePTFE has a long track record of safety with contact with intra-abdominal viscera and the development of the adhesion barrier coated mesh prosthesis has made intra-abdominal placement more attractive.

Entrance to the abdominal cavity followed by adhesiolysis can be problematic for a surgeon performing a laparoscopic ventral hernia repair and devastating complications are possible, which is the Achilles heel of this operation. This is because patients with incisional hernias by definition have had previous abdominal surgery and the midline is commonly not usable for initial access because of a previous incision in the area. The surgeon must make an educated guess as to the least likely place for significant adhesions as well as be familiar with alternate access techniques away from the midline. Unrecognized visceral injury can be the consequence if extreme care about entrance and adhesiolysis is not maintained. These injuries commonly go undetected until the patient develops signs of septic shock because it is difficult to differentiate peritoneal signs from ordinary postoperative pain. This accounts for the significant mortality with this complication. Surgeons performing laparoscopic ventral hernia repairs must have the good judgment to abandon the procedure in the face of a hostile abdomen.

Once the abdomen has been safely entered and the adhesiolysis completed, the abdominal contents are reduced from the hernia defect under direct laparoscopic guidance. The number and location of the sites of cannula placement vary depending on the size and location of the hernia. Multiple “swiss cheese defects” are the best indication for the operation because if there is only one or two defects with wide separation of the muscles, the operation is not as effective for two reasons: (a)

the prosthesis will tend to balloon out through this defect, simulating a recurrence even though the hernia is technically repaired, and (b) abdominal wall dynamics are addressed more effectively if the muscles can be reapproximated. The muscles can commonly be approximated using a suture passer/trocar site closing device similar to that demonstrated in Figure 71.36. Our group favors conversion to an open, conventional operation in situations where it is not possible to reapproximate the muscles, but this philosophy is not shared by all.

The prosthesis is prepared by placing sutures extracorporeally around its circumference with long tails extending from the nonadhesion barrier side. It is then rolled up and introduced through the largest cannula. After it is unrolled, a suture passer is introduced into the abdomen to grasp each of the suture tails through a single stab incision but separate musculofascial openings in array, which corresponds to the previously placed prosthesis sutures (Fig. 71.36). The sutures can be tied extracorporeally and the knot allowed to retract back into the subcutaneous tissue of the stab incisions. The skin is then closed over them. It is important that the prosthesis be positioned onto the peritoneum so that it widely overlaps the hernia defect (4 to 6 cm, at least). The prosthesis is further secured to the anterior abdominal wall with staples, tacks, or sutures using the suture passer technique.

Complex hernias can be challenging, especially when obesity or a question of loss of domain complicates the problem. An abdominal wall hernia is said to have lost its “right of domain” when so much of the intra-abdominal contents reside outside of the peritoneal cavity in the subcutaneous tissue that there is a question that it can be returned (see section on large hernias). These patients might best be seen in centers with special interest in this area where teams have been assembled to treat complex abdominal wall pathologies.⁷³

PARASTOMAL HERNIAS

Parastomal hernias are one of the most common complications of stoma formation. Studies designed with very careful follow-up suggest that a paracolostomy hernia develops in more than 50% of patients followed for longer than 5 years.⁷⁴ The rate of herniation with small-bowel stomas is less than for

colon stomas. Poor site selection or technical errors, such as making the fascial opening too large or placing a stoma in an incision, account for some of these hernias. Placing a stoma lateral to the rectus sheath is widely touted as a cause, but this is now being challenged. Obesity, malnutrition, advanced age, collagen abnormalities, postoperative sepsis, abdominal distention, constipation, obstructive uropathy, steroid use, and chronic lung disease also contribute. Novel techniques for stomal reconstruction, such as extraperitoneal tunneling, have had little impact.

Fortunately, patients tolerate these hernias well, and life-threatening complications, such as bowel obstruction or strangulation, are rare. Fewer than 20% of patients with parastomal hernias have a complication that mandates repair. Routine repair is therefore not recommended. Table 71.9 lists possible indications. The three general types of stomal hernia repair are fascial repair, stomal relocation, and prosthetic repair. Fascial repair involves a local exploration around the stoma site, with primary closure of the defect. This approach should be considered of historical interest only. Stomal relocation produces better results than simple fascial repair.⁷⁴ This approach is especially indicated in patients with other stomal problems, such as skin excoriation or suboptimal stomal construction. The major drawbacks of stomal relocation are the fact that a laparotomy is required, which in and of itself causes more morbidity than some of the other techniques, and it exposes the patient to the risk of three new incisional hernias at (a) the old stoma site, (b) the laparotomy incision site, and (c) the new stoma site.⁷⁵

Whenever possible, a prosthetic repair should be considered as this appears to be the most effective, although few randomized trials have been performed to unequivocally prove this. Options for the location of mesh placement in parastomal hernia repair are as follows:

1. Onlay with the mesh placed anterior to the anterior rectus aponeurosis. A hockey-stick incision is usually performed outside the boundaries of the patient's appliance (Fig. 71.37). The skin and subcutaneous tissue are then undermined to identify the fascial defect, which is closed primarily and reinforced with a prosthetic onlay. The problem with this approach is that the undermining of subcutaneous tissue leads to seroma formation, which sometimes goes on to infection.
2. Inlay with the mesh placed to bridge the defect and sutured to the fascial edges. This alternative has in multiple series been shown to have the highest chance of recurrence and suffers from the seroma problem, as with the onlay.

FIGURE 71.37. Repair of a parastomal hernia. **A:** Incision around hernia. **B:** Hernial sac is identified, the contents are reduced, and the peritoneum is closed. **C:** The edges of the fascial defect are reapproximated. **D:** The fascial repair is reinforced with polypropylene mesh, which is wrapped around the subcutaneous portion of the colon and sutured in place. (After Pearl RK. Para-stomal hernias. *World J Surg* 1989;13:569.)

3. Sublay with the mesh placed dorsal to the rectus muscle and anterior to the posterior rectus sheath.
4. Intraperitoneal inlay mesh (IPOM). An intra-abdominal prosthetic repair eliminates the need for the abdominal wall dissection and is therefore becoming increasingly popular. It also enlists the mechanical advantage of placing the prosthesis on the peritoneal side of the abdominal wall.⁷⁶ The intra-abdominal approach is particularly suited for laparoscopy, and several techniques have been described.⁷⁷

Janes performed a prospective randomized study using a prophylactic mesh when constructing stomas. He randomized 54 patients to a conventional stoma construction versus the same with the addition of a lightweight, wide-pore prosthesis in a sublay position. He reported that after 5 years, 17 out of 21 patients with the conventional technique had recurred compared to only 2 out of 15 patients in the prophylactic group. There were no fistulas, strictures, or wound infections during the study period.⁷⁸

UNUSUAL HERNIAS

Spigelian Hernia

A Flemish anatomist, Adriaan van der Spiegel, first described the semilunar line, which is the lower limit of the posterior rectus sheath. Also called the spontaneous lateral ventral hernia, a spigelian hernia protrudes through an area of weakness just lateral to the rectus sheath and just below this line (Fig. 71.38). The hernia is usually interparietal, rarely

FIGURE 71.38. Spigelian hernia. **A:** Usual site of occurrence. **B:** Transverse section of abdominal wall showing site of defect.

penetrating the external oblique fascia, and therefore can be difficult to appreciate. Most of the time, this hernia appears below the arcuate line. This is an unusual hernia; only 744 cases have been described in the literature. The usual presentation is lower abdominal swelling just lateral to the border of the rectus muscle. Spigelian hernias often occur in elderly female patients. They are usually small, about 1 to 2 cm in diameter, although large hernias up to 14 cm in diameter have been described. Omentum and small or large bowel may enter the sac. Incarceration and strangulation are common complications of this hernia. Because the hernia is deep to the external oblique fascia, the clinical presentation may not be obvious. Pain and tenderness may be the only signs. Plain roentgenograms may show a bowel shadow in this area, and CT can demonstrate the defect well. Treatment is operative repair. A transverse incision is centered over the mass. The external oblique aponeurosis is split to reveal the protrusion. If a large sac is present, it is divided and sutured. The aponeurotic defect is triangular, with its base at or near the lateral border of the rectus muscle. The defect is closed by joining the separated transversus and internal oblique layers. Another option is a laparoscopic repair, done using an intra-abdominal or preperitoneal approach. Recurrence is uncommon.

Lumbar Hernia

The lumbar region is the area bounded inferiorly by the iliac crest and superiorly by the 12th rib, posteriorly by the erector spinae group of muscles, and anteriorly by the edge of the external oblique muscle as it extends from the 12th rib to the iliac crest. The three varieties of lumbar hernia are described in Table 71.10. These hernias require repair if they are large, and

because of the size of the defect, synthetic mesh is used. For the inferior lumbar hernia, a rotation flap of fascia lata can be used (Fig. 71.39).

Obturator Hernia

This hernia is the result of abdominal contents protruding through the obturator canal in the pelvis. This canal is the opening in the superior part of the obturator membrane covering the foramen formed by the union of the pubic bone and ischium, through which the obturator nerve, artery, and vein pass from the pelvic cavity into the thigh. A recent history of profound asthenia and weight loss is not unusual, which is most likely due to the loss of the protective fat in the obturator canal.⁷⁹ This may account for the fact that women are more often than men afflicted with this hernia because their broader pelvis results in a larger obturator canal. The diagnosis of an obturator hernia is difficult because it is rare and physical examination is rarely helpful because the associated mass is concealed beneath the adductor muscles of the thigh. The main symptom is intermittent pain. The defect is approached transperitoneally; the hernia is reduced and mesh placed over the defect. Depending on the expertise of the responsible surgeon, either a conventional open or laparoscopic operation is reasonable.

Sciatic Hernia

A sciatic hernia is a protrusion of a peritoneal sac through the major or minor sciatic foramen (Fig. 71.40). These very rare hernias present with a swelling on the buttock. The sciatic nerve may be involved. A ureter can become obstructed if it is included with the herniated tissues. The treatment of these

TABLE 71.10

TYPES OF LUMBAR HERNIA

■ TYPE	■ DESCRIPTION
Superior lumbar hernia of Grynfeltt	Occurs through a space between the latissimus dorsi, the serratus posterior inferior, and the posterior border of the internal oblique muscle
Inferior lumbar hernia of Petit	Occurs through a defect in the space bounded by the latissimus dorsi posteriorly, the iliac crest inferiorly, and the posterior border of the external oblique anteriorly
Secondary lumbar hernia	Develops as a result of trauma, mostly surgical (e.g., renal surgery), or infection; lumbar hernias were encountered relatively frequently in the past in cases of spinal tuberculosis with paraspinal abscesses

FIGURE 71.39. Technique of repair of inferior lumbar hernia.

hernias is surgical. Both transperitoneal and transgluteal approaches have been described. A combination of the two is sometimes used. The defect usually requires a prosthetic mesh repair.

Supravesical Hernia

This hernia is anterior to the urinary bladder and forms when the integrity of the transversus abdominis muscle and the transversalis fascia fail, both of which insert into the Cooper ligament. The preperitoneal space is continuous with the retropubic space of Retzius, and the hernial sac protrudes into this area. The sac of the hernia is directed laterally, emerges at the lateral border of the rectus muscle, and presents in the inguinal, femoral, or obturator region. It can also be associated with an inguinal, femoral, or obturator hernia. Treatment of this hernia depends on recognizing it at the time of groin exploration and reinforcing the defect.

A second variety of these hernias is known as an internal supravesical hernia. They are classified according to whether they cross in front of, beside, or behind the bladder (Fig. 71.41). Bowel symptoms predominate in patients with these hernias, and urinary tract symptoms develop in up to 30%. The treatment is surgical, and a transperitoneal approach is used through a low midline incision. The hernias can usually be reduced without difficulty. The neck of the sac should be divided and closed.

Interparietal Hernia

This hernia is one in which the hernial sac lies between the layers of the abdominal wall. It may be either *preperitoneal* (between the peritoneum and the transversalis fascia) or *interstitial* (between the muscle layers of the abdominal wall). The majority are inguinal, in which case they are designated *inguinal interstitial* hernias. An *inguinal crural* hernia occurs

FIGURE 71.40. Sciatic hernia. 1, Suprapiriform. 2, Infrapiriform. 3, Subspinous.

when the sac passes behind the inguinal ligament in the region of the femoral ring.

The cause of these hernias appears to be related to congenital abnormalities; they have been associated with failure of the testis to descend, congenital pouches, and other abnormalities, such as absence of the cremaster and absence of the external abdominal ring.

The diagnosis of these hernias is difficult because no swelling of the abdominal wall is obvious unless the hernia is large. Pain is commonly the only symptom, and it is not unusual for patients to present with intestinal obstruction secondary to incarceration. CT, ultrasonography, and laparoscopy can be helpful in making the diagnosis. Not infrequently, the correct diagnosis is made only at operation. The defect is repaired according to the principles described for inguinal and incisional hernias.

diverticulum is symptomatic or strangulated, then it is mandatory to resect it at the time of the hernia repair.

Perineal Hernia

These hernias are more common in older female patients and are related to a lax pelvic floor. They are termed *anterior* or *posterior* according to their relationship to the transversus perinei muscle. The anterior hernias usually present as a swelling in the labium or lateral vaginal wall. The posterior hernias present between the rectum and the ischial tuberosity. Surgical repair requires a transperitoneal approach, and, if the opening is large, a prosthetic mesh repair is required.

Perivascular Hernia

These hernias present through defects between the inguinal ligament and the iliopubic bone. They are known by various eponyms according to their position. The hernia protruding through a defect in the lacunar ligament is *Laugier hernia*.

Littre Hernia

Littre hernia is a groin hernia containing a Meckel diverticulum. These hernias sometimes also contain the appendix. If the

FIGURE 71.42. Perivascular hernias and their eponyms.

The hernia protruding through the pectineal fascia is *Cloquet hernia*. The hernia extending anterior to the femoral vessels but behind the inguinal ligament is *Velpeau hernia*. The hernia behind the vessels is *Serafini hernia*. Lateral to the femoral artery are two hernias, the anterior one being *Hesselbach hernia* and the more posterior one *Partridge hernia* (Fig. 71.42).

Complications of Repair

The complications of abdominal wall hernia repair are many and varied (Table 71.11), but fortunately uncommon. The complications of herniorrhaphy can be categorized according to whether they are related to the laparoscopy, the patient, or the herniorrhaphy. Except for the complications unique to laparoscopy, complications occur at similar rates in both laparoscopic and conventional procedures.

Complications Related to Laparoscopy

Vascular Injury. These are for the most part related to access. The most serious injuries occur to vessels that reside in the retroperitoneum. For all laparoscopic procedures, the risk for major vascular injury that requires operative intervention is 0.9 per 1,000 cases.⁸⁰ The vessels most at risk are the distal aorta, common iliac arteries and veins, and inferior vena cava and the inferior epigastric vessels. Injuries to the renal vessels have also been reported. These vessels are fixed and may be penetrated even if the safety mechanisms of the needle or trocar are working properly. The mesenteric and omental vessels are also at risk, especially in the presence of adhesions. The epigastric arteries may be injured with secondary cannula placement.

The insufflation needle is the most common cause of vascular injury but may be self-limiting; on the other hand, injuries caused by a trocar are usually more obvious and catastrophic. The mortality associated with retroperitoneal injury secondary to trocar insertion ranges from 9% to 36%, even with rapid identification and repair. When suspected, immediate conventional laparotomy is almost always indicated. Most abdominal wall vascular complications occur during the placement of secondary cannulae. Usually, pressure can be applied to bleeding at the trocar site with the cannula. Occasionally, suture ligation is required, which has been simplified by the development of disposable “exit devices” designed to facilitate the placement of fascial sutures. Most of these complications can be avoided by placing the secondary trocars under direct vision.

Gas Embolism. This is caused by intravascular insufflation.⁸¹ It is an uncommon complication, unique to the needle insufflation

TABLE 71.11

COMPLICATIONS

COMPLICATIONS OF LAPAROSCOPIC HERNIORRHAPHY

RELATED TO LAPAROSCOPY	RELATED TO HERNIORRHAPHY

technique. Careful attention to tests confirming proper peritoneal needle placement will keep the incidence of this complication low.

Visceral Injury. Visceral injuries are uncommon, occurring in 1.8 per 1,000 cases of all laparoscopic procedures, but they have a mortality rate of 5%.⁸⁰ The most common means of injury is the insufflation needle. Simple repair laparoscopically is usually possible as most are self-limiting. If the injury is caused by a trocar, formal repair of the injury will be needed. The injury can be repaired laparoscopically if the skill of the laparoscopic surgeon is sufficient. Otherwise, laparotomy is mandatory. Quite often, these injuries go unnoticed at the time of insult, so that visceral injury is the most common cause of late morbidity and mortality associated with laparoscopic access. Patients typically present with peritonitis and sepsis 2 days to 1 week after surgery.

Bladder Injury. Bladder injury can be the result of a laparoscopic misadventure or can be directly related to the herniorrhaphy. Laparoscopic peritoneal access can result in a bladder perforation, usually the result of failure to decompress a distended bladder. Less commonly, injury is associated with a congenital bladder abnormality. Bladder injury has not been reported with the open access technique. Injury to the bladder can also occur during secondary suprapubic trocar placement during the course of an operation. When bladder injury occurs, it is usually obvious. After Veress needle insertion, urine is withdrawn into the syringe, or blood and gas are noticed in the urine if the patient is catheterized. In questionable cases, methylene blue dye may be instilled into the bladder to look for leakage. Bladder injury recognized during laparoscopy should be repaired laparoscopically provided the experience of the surgeon is sufficient. This should be followed by bladder drainage for 7 to 10 days.

Bladder injury may present in a delayed fashion with hematuria and lower abdominal discomfort. A retrograde cystogram usually confirms the diagnosis. Small defects may be managed with postoperative decompression via an indwelling catheter for urinary drainage, while larger defects necessitate repair. The bladder is especially prone to injury during preperitoneal herniorrhaphies or when the preperitoneal space has previously been dissected (e.g., previous preperitoneal hernia repair or prostatectomy).⁸²

Bowel Obstruction. This problem plagued the developmental stages of laparoscopic inguinal herniorrhaphy for two reasons. First, the importance of closing trocar sites at the fascial level if greater than 5 mm was not appreciated, resulting in the occasional patient with an incarcerated or strangulated ventral hernia at the trocar site, leading to the clinical presentation of a bowel obstruction. There are now several different types of reusable and disposable appliances designed to facilitate trocar site fascial closure, which should minimize the incidence of these hernias (Fig. 71.36). The second is inadequate peritoneal closure over the prosthesis, which allows bowel to migrate into the preperitoneal space, also resulting in intestinal obstruction. Steps taken to avoid tension at the peritoneal closure site (see TAPP technique section) have decreased this problem. Theoretically, the TEP procedure eliminates the possibility of this complication because the abdomen is not entered. However, inadvertent breaches of the peritoneum during a TEP herniorrhaphy are common, especially in patients with thin peritoneum or those who have scar tissue associated with previous lower abdominal surgery. These peritoneal lacerations can be difficult to recognize because they are not in the visual field of the limited working space, and indeed intestinal obstruction has been reported.⁸³

Diaphragmatic Dysfunction. Phrenic nerve palsy has been reported with a variety of laparoscopic procedures; it is usually

transient but has been known to require a short period of mechanical ventilation. Stretching during the pneumoperitoneum probably causes this complication.

Hypercapnia. This is the result of inadequate compensatory ventilation given the fact that, in the vast majority of laparoscopic procedures, carbon dioxide is used as the insufflating agent.

Complications Related to the Patient

Urinary Retention. The most common predisposing factor for urinary retention after a hernia repair is the use of general or regional anesthesia.⁴⁴ It is more common after groin than abdominal wall hernia repairs. Meta-analyses of randomized controlled trials comparing various hernia techniques have not shown a difference in urinary retention rates. Jensen et al. published a review of the literature on urinary retention after inguinal herniorrhaphy from 1966 to 2001. Pooled data from 70 nonrandomized and two randomized studies disclosed that the incidence of urinary retention with local anesthesia was 0.37% (33 in 8,991 patients), with regional anesthesia 2.42% (150 in 6,191 patients), and with general anesthesia 3% (344 in 11,471 patients).⁸⁴ The incidence varies widely from as low as 1% to over 20%.^{85,86} For example, in a series of laparoscopic inguinal hernia repairs, Koch et al. noted a 22.2% incidence of urinary retention.⁸⁷ All cases were done under general anesthesia and postoperative use of narcotics and the administration of postoperative intravenous fluid greater than 500 mL were found to be predictive. Demographic data including age, predisposition to urinary retention, type of procedure (TEP vs. TAPP), surgical time, anesthesia time, use of a Foley catheter intraoperatively, intraoperative fluid restriction, and the development of other complications were not significant risk factors. In addition to overhydration with intravenous fluid and opiates, other studies have found older age and prostatic symptoms to be predictive as predisposing factors.

Intermittent catheterization or temporary placement of an indwelling urinary catheter is usually adequate therapy. Prophylactic use of prazosin after herniorrhaphy may significantly reduce the incidence of urinary retention and the need for catheterization.⁸⁸ Phenoxybenzamine hydrochloride, another α -adrenergic blocker, has also been used both prophylactically and therapeutically.

Ileus. Ileus can be seen with either the conventional or the laparoscopic procedure but is more common with the latter. Treatment is symptomatic, and spontaneous resolution is the rule. Nasogastric decompression is occasionally needed.

Complications Related to the Herniorrhaphy

Recurrence. A lower risk for recurrence with the use of prosthetic material for the repair of an inguinal hernia has been clearly proven by meta-analysis.⁸⁹ Recurrence rates of 2% or less are now routinely reported from specialty centers performing either laparoscopic or conventional tension-free repairs. Although the recurrence rate for hernia repairs is less than 1% at the Shouldice Clinic, others have not been able to duplicate this outstanding record with this or any of the other nonprosthetic repairs.⁹⁰ Complications during the first month after surgery; operation for recurrence; and sutured repairs without mesh, either anterior or preperitoneal techniques, are associated with an increased recurrence rate. A laparoscopic approach is also considered a risk for recurrence because of its higher potential for technical failure, especially in the less experienced. This was felt to be the most likely reason for a higher recurrence rate at 2 years in a Veterans Affairs study for the laparoscopic approach (10%) compared to an open tension-free repair (4% for the Lichtenstein repair).⁹¹

A consistent definition of a recurrent hernia does not exist because of the difficulty in differentiating a lipoma of the cord, a seroma, or an expansile bulge of the internal oblique muscle from a true hernia recurrence. A hernia should not be classified recurrent unless there is a visible bulge or there is unequivocal evidence of a hernia by an imaging modality such as ultrasound, CT, or MRI. This is especially important for patients who present with pain after their hernia repair because their pain is likely due to a preoperative condition or a postinguinal herniorrhaphy pain syndrome and might be exacerbated by further groin surgery. Femoral recurrences are occasionally seen after a Lichtenstein repair because the femoral canal is not routinely closed with the classic technique.

The general principle for managing recurrent hernias depends on the original repair. The logical approach is to perform the herniorrhaphy in the space that has not been dissected. If the patient had a previous conventional repair, then a preperitoneal repair is best chosen. On the other hand, if the index operation was a preperitoneal one, then a repair that is performed in the conventional inguinal space is best. The dissection of the preperitoneal space after a failed herniorrhaphy has been performed there is particularly challenging, with significant risk for vascular, neurologic, and bladder injury.

Several other factors contribute to the poor results obtained in repairing incisional hernias. These include preexisting comorbid conditions, including debilitation from cancer, morbid obesity, the use of steroids, and chemotherapy. Another factor related to recurrence is lateral detachment of the mesh and inadequate mesh fixation caused by mesh distraction.⁹² This is more commonly seen in the inlay techniques.⁵⁵

9 Postherniorrhaphy Groin Pain. Now that the recurrence rate has been brought down to a minimum using modern hernioplasty techniques, chronic postoperative groin pain syndromes have emerged as the biggest issue facing inguinal hernia surgeons. Poobalan et al. published a critical review of inguinal herniorrhaphy studies between 1987 and 2000.⁹³ The frequency of at least some long-term groin pain was as high as 53% at 1 year (range, 0% to 53%). On average, moderate or severe postinguinal herniorrhaphy groin pain probably occurs in about 10% of patients. Perhaps the most important single determination for the postherniorrhaphy patient is to decide if the pain is the same or different from that which brought the hernia to the attention of the physician in the first place. There are a variety of conditions that cause groin pain (Table 71.6). CT, ultrasonography, herniography, laparoscopy, and MRI all have their place in the evaluation of these patients. MRI is perhaps the most beneficial because of its ability to differentiate between muscle tear, osteitis pubis, bursitis, and stress fracture. Strain of the adductor muscle complex (adductor longus, brevis, magnus, and gracilis muscles) is commonly overlooked in this group.

True postherniorrhaphy groin pain should be divided into two types: (a) nociceptive pain, which is caused by tissue damage and is further subdivided into somatic and visceral, and (b) neuropathic pain due to direct nerve damage. Somatic pain is the most common and is usually caused by damage to ligaments, tendons, and muscles. Visceral pain refers to that which is related to a specific visceral function such as urination or ejaculation (see dys ejaculation syndrome, later). Neuropathic pain is much less common but is important to recognize because surgical treatment is possible if the cause is incorporation of a nerve in staples or suture material. The nerves that are usually involved are the ilioinguinal nerve, the iliohypogastric nerve, both the genital and femoral branches of the genitofemoral nerve, and the lateral cutaneous nerve of the thigh. The former two are especially prone to injury during a conventional herniorrhaphy, whereas the latter are most likely damaged during laparoscopy. A femoral nerve injury is extremely rare and is usually the result of a gross technical misadventure. Pain and/or paraesthesia in their distribution characterize patients' symptoms for the more common nerves. There is significant overlap of these nerves, and therefore it is commonly difficult

to sort out exactly which nerve is damaged. Both nociceptive and neuropathic pain is best treated initially with reassurance and conservative treatment with anti-inflammatory medications and local nerve blocks because these will frequently resolve spontaneously. An exception is the patient who complains of severe pain immediately (i.e., in the recovery room). This patient may be best served by immediate reexploration before scar tissue develops. When groin exploration is required, neurectomy and neuroma excision, adhesiolysis, and foreign body removal (i.e., mesh) are options for treatment. The results are often less than satisfying.

Cord and Testicles

Infertility. The cause of infertility can be related to either the vas deferens or the testicle. The incidence of injury to the vas deferens during inguinal herniorrhaphy has been estimated at 0.3% for adults and between 0.8% and 2.0% for children.⁹⁴ Injuries to the vas deferens that may present as an obstruction include division, ligation, clipping, stapling, electrocauterization, devascularization, and scarification. In addition, there is evidence that there is a small subset of patients whose inflammatory response to mesh is so severe that vasal obstruction results.⁹⁵ Obstruction is not the only reason why an injury to the vas deferens may lead to infertility. For example, traction injuries during normal cord mobilization may damage the muscular layer of the vas deferens, which then interferes with rapid sperm transfer during ejaculation.⁹⁶ Sperm antibodies may develop as a result of extravasation of sperm at an injury site, which is why a unilateral injury can also result in infertility.

10 Ischemic Orchitis. Damage to the blood supply of the testicle can cause ischemic orchitis and testicular atrophy.⁹⁷ Ischemic orchitis occurs in about 1% of primary hernioplasties but is much more common with operations performed for recurrent hernias.⁹⁸ It manifests as postoperative inflammation of the testicle developing within 1 to 2 days after surgery. The patient has a painfully enlarged testicle that is hard in consistency and associated with low-grade fever. Pain is severe and may last several weeks. Ischemic orchitis is caused by thrombosis of the veins draining the testicle after extensive dissection of the spermatic cord. It is generally accepted that the incidence can be decreased by division of large inguinal-scrotal sacs leaving the distal sac open in situ rather than excising it.⁹⁹ The majority of patients with testicular swelling as an immediate complication of herniorrhaphy recover without testicular atrophy. In one recent report, testicular atrophy developed in 19 patients among 52,583 primary inguinal hernia repairs (0.036%) and 33 patients among 7,169 recurrent inguinal hernia repairs (0.46%).⁹⁸ A substantial number of patients who develop testicular atrophy after inguinal herniorrhaphy have no history of a testicular problem at the time of the index operation. The management of a patient with ischemic orchitis is usually conservative with elevation and anti-inflammatory medication. Antibiotics and steroids have been used but their value is unproved.

Miscellaneous. Hydroceles occasionally develop after inguinal herniorrhaphy, but the cause is not known and therefore a preventative measure is not possible. The urologic literature suggests that the practice of leaving the distal aspect of an indirect inguinal sac in situ rather than removing it should be incriminated, but this is not accepted by most experienced hernia surgeons. The treatment is the same as for any other hydrocele. Testicular descent is a complication felt to be related to complete division of the cremasteric muscle, but the occurrence is variable. The cord structures lose their tethering effect, allowing the testicle to descend into the most dependent portion of the scrotum. Due to the elasticity of the scrotum, with time gravity causes the scrotum to elongate. Patients complain their testicle "drops into the toilet" and can be quite unhappy. Few hernia surgeons now routinely completely divide the cremasteric muscle,

so it is hoped that this will become a rare phenomena. The dys-ejaculation syndrome is characterized by searing, burning, painful sensations throughout the groin around the time of ejaculation. The incidence is approximately 0.04%.⁹⁸

Wound Infection. This is a surprisingly rare complication of groin herniorrhaphy (<5%) and the reason for the “protected” status, especially when compared to prosthetic ventral herniorrhaphy, is not known.⁹⁹ Most cases of necrotizing fascitis following inguinal hernia repair have been associated either with strangulated bowel or appendicitis in the hernial sac. Necrotizing fascitis has only previously been reported in a few cases following elective hernia repair. On the other hand, the incidence of infection for incisional hernia is much higher, in the range of 10% to 15%, and is probably related to wound ischemia due to the required flap dissection. Other factors leading to infection are preexisting infection or ulceration of the skin over the hernia, obesity, incarcerated or obstructed bowel within the hernia, and perforation of the bowel at the time of hernia repair. Seromas are common when a large prosthesis is required or flap dissection of the subcutaneous layer from the fascia has been extensive. Untreated seromas can become secondarily infected. Suction drains can be useful, but if left in place too long, they also result in infection of the prosthesis. Strategies to prevent and manage seromas are largely based on empiricism and personal opinion, as objective data are nearly absent. It is not always necessary to remove the mesh prosthesis in the presence of infection. A trial of local wound care after opening of the incision and débridement is warranted.

Seromas. Seromas are common with the use of synthetic mesh in laparoscopic hernia repairs and are possibly related to the size of the mesh used. The fluid eventually resorbs spontaneously. Aspiration is performed for symptomatic relief only.

Bleeding. Hemorrhage can occur from the cremasteric, internal spermatic, or inferior epigastric vessels. Conservative treatment with reassurance is preferred for a stable hematoma. Evacuation is rarely required. Injuries to the deep circumflex artery, the corona mortis, or the external iliac vessels may result in a large retroperitoneal hematoma.

Prosthetic Complications. Shrinkage of polypropylene and other meshes should be considered by surgeons when performing prosthetic repairs. Sufficient overlap anticipating a 20% contracture is accepted by most. The decrease in size is felt to be due to scarification of the recipient's tissue. Intestinal obstruction or fistulization is possible by erosion, especially if there is physical contact between intestine and the prosthesis. Intra-abdominal placement of a mesh prosthesis should be avoided in favor of ePTFE or perhaps a biologic prosthesis whenever possible. Rejection because of an allergic response is possible but extremely rare. What patients cite as “rejection” of the mesh is usually the result of infection. Local erosion into the cord structures has also been reported.¹⁰⁰

CHAPTER 72 ■ ACUTE ABDOMEN AND APPENDIX

JEFFREY B. MATTHEWS AND RICHARD A. HODIN

KEY POINTS

- 1 Pathologic processes affecting abdominal viscera that produce abdominal pain with characteristic symptoms and signs include obstruction, inflammation, perforation, torsion, and ischemia.
- 2 Acute abdominal pain in immunosuppressed patients presents a particular diagnostic challenge both in making the diagnosis and due to the unusual infectious causes of abdominal pain that may be present.
- 3 The cause of acute appendicitis in most patients is luminal obstruction that leads to bacterial overgrowth and increased luminal pressure, leading to obstruction of venous outflow and then arterial inflow, resulting in gangrene and eventual perforation.
- 4 Ultrasonographic findings of acute appendicitis include demonstration of a so-called target lesion (i.e., a thick-walled, noncompressible, luminal structure in the right lower quadrant with peritoneal fluid and even frank abscess in advanced cases).
- 5 Computed tomography scanning has become the imaging modality of choice for patients with suspected acute appendicitis. It is highly accurate with sensitivities and specificities reported in the ranges of 95% to 100%.
- 6 A number of studies suggest that laparoscopic appendectomy is associated with a benefit in regard to shorter hospital stay, narcotic use, and overall recovery, with a perioperative complication rate comparable to open appendectomy.
- 7 A patient presenting late with appendicitis and an appendiceal mass should undergo initial percutaneous drainage and intravenous antibiotics followed by interval appendectomy in about 8 to 12 weeks.
- 8 The diagnosis of acute appendicitis in children is difficult, leading to a perforation rate as high as 50%.
- 9 The diagnosis of acute appendicitis in the elderly is difficult, leading to a perforation rate as high as 50% and higher associated rates of morbidity and mortality.
- 10 Appendicitis is the most frequent nonobstetric indication for laparotomy during pregnancy and the difficulty in diagnosis leads to a high perforation rate and associated high fetal mortality.
- 11 Carcinoid tumors less than 1.5 cm are adequately treated by appendectomy, whereas tumors 2 cm in size or greater have metastatic potential and a right hemicolectomy is indicated.

APPROACH TO THE PATIENT WITH ACUTE ABDOMINAL PAIN

Abdominal pain is one of the most frequent reasons for visits to physician offices and hospital emergency rooms and is a leading cause for hospital admission in the United States. Although most patients will be found to suffer from self-limited conditions of little consequence, a subset of patients with acute abdominal pain will harbor serious intra-abdominal or retroperitoneal pathology that requires major surgical or medical intervention. It is this latter population to whom the term “acute abdomen” is commonly applied, although “abdominal emergency” might be more descriptive. The experienced clinician understands that the severity of the pain does not always correlate with the gravity of the situation, nor do all patients with the so-called acute abdomen require surgical intervention. Early diagnosis, and particularly the early distinction of conditions that require urgent operation from those best managed nonsurgically, must be the paramount principle that outweighs all other concerns. Evaluation by a surgical consultant and performance of appropriate radiologic studies must proceed promptly regardless of time of day or disruption of normal routines and schedules.¹ There is considerable interexaminer variability in the evaluation of acute abdominal pain based on the level of experience as well as on specialty (e.g., emergency medicine physician vs. surgeon).^{2,3}

In the vast majority of cases, a thorough history and physical examination will reveal the cause of the abdominal pain or at least sufficiently narrow down the possibilities to allow initial treatment decisions to be made.⁴ Important features to be elicited include the time and mode of onset of the illness,

the location of the pain, the character of the pain, and the presence of associated symptoms and their relation to the pain (Table 72.1). Examination of the patient includes an assessment of general appearance and attitude in bed in addition to the abdominal examination itself (Table 72.2). The ability to group the symptoms and signs of acute abdominal pain and to weigh their relative importance (“pattern recognition”) perhaps best distinguishes the novice from the expert diagnostician in this setting. Blood tests may be complementary but are only occasionally of major importance in the initial evaluation. The same is generally true for radiologic studies, although in some circumstances, newer techniques of abdominal imaging do appear to enhance diagnostic accuracy. However, it cannot be overstated that an excessive reliance on tests can lead to unnecessary delay and must be avoided. There is little evidence to support a benefit to decision tools such as computer-based structured checklists or algorithms in the diagnosis of acute abdominal pain.⁵ Thus, excessive ordering of tests or complex triage algorithms are unlikely to substitute for a knowledgeable, compassionate surgeon.

Most patients with acute abdominal pain evaluated in the emergency room setting will not require either hospital admission or surgical intervention.⁶ The most common causes of abdominal pain requiring admission include acute appendicitis, nonspecific abdominal pain, pain of urologic origin, intestinal obstruction, and biliary tract disease, depending on the population and geographic region considered.⁷ With improvements in diagnostic imaging over the past few decades, more patients with acute abdominal pain are able to be assigned a specific diagnosis and there are fewer instances of missed surgical disease.⁸

EMBRYOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

The developing gastrointestinal (GI) tract is divided into three regions based on blood supply and innervation, relationships that are maintained from embryonic to adult life. The foregut consists of the oropharynx, esophagus, stomach, proximal duodenum, pancreas, liver, biliary tract, and spleen. The midgut runs from the distal duodenum (ligament of Treitz) and includes the small intestine, appendix, cecum, ascending colon, and proximal two thirds of the transverse colon. The remainder of the colon and rectum make up the hindgut.

The intestinal tract itself, from the stomach to the distal sigmoid colon (with the exception of the duodenum), is lined by

a layer of mesodermally derived visceral peritoneum. The liver, spleen, and gallbladder are largely covered by visceral peritoneum; the pancreas is located within the retroperitoneum. Although continuous with the parietal peritoneum that lines the abdominal cavity, the visceral peritoneum is supplied by autonomic (sympathetic and parasympathetic) nerves. In contrast, the parietal peritoneal layer has an entirely somatic innervation derived from spinal nerves. This difference accounts for the distinct character of the pain associated with irritation or inflammation of the parietal peritoneum (which is generally perceived as sharp, severe, and persistent) compared to painful stimuli involving the visceral peritoneum (perceived as dull, cramping or aching, and poorly localized, and often associated with nausea and/or diaphoresis). The visceral peritoneum and its associated organs are insensitive to touching, pinching, cutting, burning, and electrical stimulation, but the sensation of pain from these sites can be induced by stretching, distention, or vigorous contraction against resistance. Additional painful stimuli to visceral organs include certain chemicals, ischemia, and inflammation. Visceral pain usually indicates the presence of significant intra-abdominal disease but is not in itself an indication for surgical therapy. A transition from visceral to somatic pain implies extension of the underlying disease process to include the parietal peritoneum and often heralds the need for urgent operative intervention (e.g., acute appendicitis, intestinal obstruction with strangulation). However, somatic pain of intra-abdominal origin should not be equated with the invariable need for operation (e.g., acute diverticulitis). In this regard, it is important to distinguish between localized somatic pain and diffuse somatic pain. Although conditions associated with localized peritonitis may require operation, the degree of urgency is far less than in diffuse peritonitis, which almost always indicates a surgical emergency.

The central gut tube is invested with a bilateral nerve supply, accounting for the midline location of the visceral pain originating from these organs. Pain of foregut origin is usually perceived in the epigastrium, midgut pain in the periumbilical region, and hindgut pain in the hypogastrium. In contrast, pain deriving from the bladder, prostate, uterus, ovaries, and fallopian tubes may be localized as pelvic or, occasionally, perineal. Pain originating from the abdominal wall musculature or parietal peritoneum is usually perceived in precise relation to the anatomic location of the stimulus because somatic pain nerve fibers enter the spinal cord ipsilaterally. The anterior and lateral abdominal wall is innervated from vertebral segments T7 to L1, whereas the posterior abdominal wall is from L2 to L5.

In addition to pain of the somatic and visceral categories, a third form of pain related to acute abdominal disorders is referred pain. Referred pain is perceived at a site removed from the anatomic location of the pathology but in a region that shares a common embryonic origin. The most common example is the radiation of pain of biliary origin to the right subscapular region or right shoulder. This phenomenon reflects the fact that the phrenic nerve is derived from the fourth cervical nerve. Thus, irritation of the undersurface of the right hemidiaphragm, such as by an inflamed gallbladder or hepatic abscess, may induce pain or hyperesthesia in the skin distribution of the fourth cervical nerve. Similarly, splenic pathology (e.g., rupture) may be perceived as pain in the left shoulder (Kehr sign). Other examples of referred pain are listed in Table 72.3.

Inflammation of the parietal peritoneum leads to rigidity and tenderness of the overlying muscle groups, a phenomenon of great clinical significance in the diagnosis of acute abdominal pain. These include not only the muscles of the anterior abdominal wall such as the rectus abdominus but also the diaphragm, psoas, quadratus lumborum, erector spinae, pyramidalis, and obturator internus. Thus, an inflamed retrocecal appendix overlying the right psoas muscle may produce spasm reflected by the preference of the patient to maintain the right thigh in flexed position; in addition, placing the patient on the

TABLE 72.3

DIAGNOSIS

SITES OF REFERRED PAIN

SITE	ORGAN(S)	COMMON EXAMPLES
Right subscapular or shoulder	Diaphragm, gallbladder, liver	Biliary colic, perforated ulcer, pneumoperitoneum
Left subscapular or shoulder	Diaphragm, spleen, stomach, tail of pancreas, splenic flexure	Splenic rupture, pancreatitis
Back	Pancreas, duodenum, aorta	Pancreatitis, ruptured AAA
Coccyx	Uterus, rectum	Uterine colic
Groin or genitalia	Kidney, ureter, iliac arteries	Ureterolithiasis

AAA, abdominal aortic aneurysm.

left side and fully extending the right thigh may produce pain (psoas sign). Similarly, the presence of an inflamed appendix or periappendiceal abscess may be deduced by a positive finding in the so-called obturator test (pain on internal rotation of the right thigh). In contrast, irritation of the deep pelvic peritoneum is generally not associated with any overlying muscle group, accounting for the striking lack of abdominal wall rigidity in cases of pelvic abscess from appendicitis or diverticulitis.

DIFFERENTIAL DIAGNOSIS

The sheer number of conditions that produce acute abdominal pain is overwhelming. However, the differential diagnosis may be narrowed substantially by anatomic considerations and an understanding of the general characteristics of the episode of the pain.

It is useful to subdivide the abdomen into four quadrants and consider the conditions that cause abdominal pain localized to each region (Table 72.4). Pain that does not lateralize in this fashion can be characterized as epigastric, periumbilical, or hypogastric, and a relatively limited differential diagnosis can also be generated for each midline location (Table 72.5). Diffuse abdominal pain (Table 72.6) can be mild and without significant physical findings, as in early acute appendicitis, or it can be severe and associated with generalized abdominal muscle rigidity, as in diffuse peritonitis.

- There are a limited number of pathologic processes affecting abdominal viscera that produce abdominal pain, and each is associated with a characteristic evolution of clinical symptoms and signs (Table 72.7). *Obstruction* of a hollow viscus results in a form of pain termed colic, consisting of a deep, nauseating ache that may be cyclical, as in intestinal colic, or steady, as in biliary colic. *Inflammation* can be the result of bacterial infection and generally produces only mild pain until the process becomes transmural, at which point the resultant peritoneal irritation can cause localized somatic pain. *Perforation* or rupture of a hollow viscus or other structure (e.g., an ovarian cyst or a hepatic adenoma) typically results in a pain of sudden onset that builds to maximum intensity over minutes to hours, producing signs of peritoneal irritation that are initially localized but may soon become generalized. *Torsion* may also produce a severe pain of sudden onset, but usually physical findings in the initial phase are limited to the site of torsion and do not generalize. Finally, *ischemia* of a solid or hollow viscus produces a severe pain frequently described as out of proportion to physical findings.

As a first step in differential diagnosis, it is useful to tentatively assign the abdominal pain episode to one of these pathologic processes and to one of the previously mentioned

locations. These categories are of course not absolute, because overlapping presentations are seen in a variety of conditions. For example, sigmoid volvulus simultaneously represents torsion and obstruction, whereas acute cholecystitis is initially due to obstruction (of the cystic duct) but then progresses to transmural inflammation. It is not unusual for a pain that is initially due to one process to evolve into another (e.g., intestinal ischemia and infarction developing as a consequence of untreated adhesive obstruction).

EVALUATION OF THE PATIENT WITH ABDOMINAL PAIN

It has been said that the most important diagnostic instrument available to the clinician is a chair, and this is perhaps nowhere more true than in the setting of the evaluation of a patient with acute abdominal pain. While eliciting the history, the clinician should take the opportunity to observe the patient's attitude in bed; the facial expression, particularly during paroxysms of pain; and the contour of the abdomen.⁴

The course of the episode of illness should be retraced, beginning with the exact time and mode of onset of the pain as well as any prodromic events occurring in the hours or days from the point at which the patient was subjectively at baseline health. The location and character of the pain, the direction of radiation of the pain, and changes in intensity or shifts in location over time are elicited. The presence of associated symptoms, in particular anorexia and vomiting, and their relation to the onset and evolution of pain are determined. Nausea and vomiting are usually due either to severe irritation of the peritoneal or mesenteric nerves or to obstruction of a hollow viscus. The character and time of the most recent bowel movement or the occurrence of diarrhea is noted. The relevant past medical history is then documented in detail, with particular attention to prior episodes of similar pain, the presence of major digestive or other systemic disorders, and previous abdominal operations. Current medications are documented. Corticosteroid use or other conditions associated with immunosuppression may diminish the symptoms produced by inflammation and obscure a serious degree of intra-abdominal disease. The presence of familial disorders or concurrent illness in family or other contacts should be noted.

The age of the patient should be taken into account, as the differential diagnosis shifts considerably when dealing with the pediatric versus the geriatric population. In women, a recent menstrual history is obtained and prior pregnancies noted. Gynecologic causes of acute abdominal pain to be considered include Mittelschmerz or ruptured ovarian cyst, pelvic inflammatory disease, ectopic pregnancy, tubo-ovarian abscess (with or without rupture), and ovarian torsion.

TABLE 72.4**DIAGNOSIS****PAIN LOCALIZING TO AN ABDOMINAL QUADRANT**

RIGHT UPPER QUADRANT PAIN	LEFT UPPER QUADRANT PAIN
Biliary colic/cholecystitis	Splenic rupture
Cholangitis	Splenic infarction
Hepatic abscess	Splenomegaly
Hepatitis (toxic or viral)	Ruptured splenic artery aneurysm
Perihepatitis (Fitzhugh-Curtis syndrome)	Gastritis
Hepatic congestion	Perforated gastric ulcer (phlegmonous gastritis)
Budd-Chiari syndrome	Jejunal diverticulitis
Hepatic tumor (primary or secondary)	Pancreatitis
Appendicitis	Diverticulitis (splenic flexure)
Perforated peptic ulcer	Perinephritis
Perinephritis	Pneumonia (left lower lobe)
Pneumonia (right lower lobe)	Pulmonary infarction
Pulmonary infarction	Pleuritis
Pleuritis	Pericarditis
Myocardial ischemia	Myocardial ischemia
Empyema	Empyema
Rib fracture	Rib fracture
Herpes zoster	Herpes zoster
RIGHT LOWER QUADRANT PAIN	LEFT LOWER QUADRANT PAIN
Appendicitis	Diverticulitis
Acute enterocolitis (viral or bacterial)	Appendicitis
Crohn disease (ileitis)	Perforated colon cancer
Foreign body perforation	Intestinal obstruction
Right-sided diverticulitis	Crohn colitis
Cecal diverticulitis	Ischemic colitis
Meckel diverticulitis	Ruptured iliac artery aneurysm
Torsion of appendix epiploica	Ruptured ovarian cyst (including Mittelschmerz)
Mesenteric adenitis	Ovarian torsion
Intestinal obstruction	Endometriosis
Perforated peptic ulcer	Salpingitis (pelvic inflammatory disease)
Pancreatitis	Ectopic pregnancy
Ruptured ovarian cyst (including Mittelschmerz)	Renal or ureteral calculi
Ovarian torsion	Pyelonephritis
Endometriosis	Psoas abscess
Salpingitis (pelvic inflammatory disease)	Seminal vesiculitis
Ectopic pregnancy	Rectus sheath hematoma
Cholecystitis	Herpes zoster
Ruptured iliac artery aneurysm	
Renal or ureteral calculi	
Pyelonephritis	
Psoas abscess	
Seminal vesiculitis

■ PROCESS	■ COMMON EXAMPLES
Obstruction	Intestinal colic, renal calculi, biliary colic
Inflammation	Enterocolitis, mesenteric adenitis
Perforation	Perforated peptic ulcer
Torsion	Ovarian torsion, sigmoid volvulus
Ischemia	Mesenteric artery thrombosis, splenic infarction

As indicated previously, the physical examination should begin with inspection of the general appearance, attitude in bed, and facial expression. Unwillingness to change position may indicate underlying peritonitis; conversely, an inability to find a comfortable position may be seen with ureteral colic due to nephrolithiasis. A patient with acute pancreatitis or mesenteric ischemia may prefer to lean forward. Intermittent grunting may be observed in a patient with intestinal obstruction. Vital signs are measured. The presence of cool, clammy skin or of jaundice may be observed at this time.

Inspection of the abdomen will reveal generalized distention or focal swelling. The presence of a hernia must be specifically excluded by direct examination of all hernial orifices and abdominal incisions. Auscultation of the abdomen may be performed next, although this only rarely provides valuable information. Auscultation of the chest, particularly the basilar regions, may reveal pneumonic consolidation that can simulate an acute abdominal process or may reveal a pleuritic rub. Gentle percussion of the abdomen will help distinguish gaseous distention from ascites; loss of dullness over the liver may indicate free intraperitoneal air, as in perforated duodenal ulcer. Tenderness to percussion, either localized or across the abdomen, suggests focal or diffuse peritonitis. Referred tenderness to percussion (pain perceived away from the site of percussion) is an extremely important finding that is essentially pathognomonic for peritonitis.

Palpation of the abdomen must be gentle. Rough or sudden deep palpation will frighten the patient, cause voluntary guarding, and hamper subsequent attempts to palpate the abdomen. The presence of subtle muscle rigidity (involuntary guarding) or of an intra-abdominal mass is more likely to be detected by a gentle approach. It may be useful to ask the patient to flex the thighs during this phase of the examination. Areas of skin hyperesthesia may be noted during gentle palpation. Elicitation of rebound tenderness rarely provides additional information beyond that obtained by careful percussion and palpation and is not recommended. The psoas and obturator tests may be performed next. In patients with a colostomy or ileostomy, direct examination of the stoma along with digitalization is important. The back is examined with attention to the presence of spinal tenderness or tenderness in the costovertebral angle or flanks.

Examination of the pelvis is extremely important in most patients with abdominal pain. Suprapubic palpation may reveal an enlarged bladder or tenderness indicative of deeper disease. Digital rectal examination may reveal focal tenderness due to a periappendiceal or peridiverticular pelvic abscess. Anterior palpation may reveal the only evidence of pelvic peritonitis, particularly in males. A bimanual vaginobdominal examination in females will reveal pathology in the pouch of Douglas or involving the uterus, tubes, or ovaries.

Whether it is prudent to administer analgesics to the patient undergoing evaluation for acute abdominal pain has remained a controversial question. Certainly, once the diagnosis is established

or a definitive plan of action has been made, it is not justifiable to withhold such treatment. There is a considerable literature to suggest that administration of morphine can provide substantial pain relief without changing important physical signs (in particular, the presence of peritoneal irritation), although there are limited high-quality prospective, randomized data.^{9–11}

Laboratory and Radiologic Examination

The common practice of ordering a “routine” panel of tests, even prior to evaluation by a physician, is wasteful of resources and may lead to unnecessary delays in diagnosis and treatment, particularly when normal values lull caregivers into a false sense of security. For example, the white blood cell count is notoriously normal in a substantial fraction of patients with serious intra-abdominal pathology and is frequently elevated in cases of nonsurgical disease.¹² However, a hematocrit and serum electrolytes and blood urea nitrogen may be useful to guide fluid resuscitation. A serum amylase and liver chemistries are usually indicated in patients with upper abdominal pain but only rarely so in lower abdominal pain. Although liberal use of human chorionic gonadotropin testing may avoid a missed tubal pregnancy, its routine use in females with abdominal pain is not likely to be cost-effective. A urinalysis is frequently of value to screen for urologic causes of abdominal pain, but routine urine culture is unnecessary.

Plain radiographs of the abdomen are ordered far in excess of their usefulness in the evaluation of abdominal pain.^{13,14} Despite occasional positive findings (e.g., air–fluid levels, a fecalith, gallstones), plain films tend to be relatively nonspecific, complementing what is already obvious on history and examination, and rarely redirect therapeutic thinking. They are most helpful in patients with suspected ureteral calculus or intestinal obstruction. It is important to remember that abdominal films are frequently normal or nondiagnostic in patients with strangulating obstruction. An upright chest film is the least expensive and perhaps best test to identify free intraperitoneal air.

Upper GI series performed with water-soluble contrast is occasionally helpful in detecting ulcer perforation and determining whether such perforation is free or contained. A water-soluble contrast enema may be useful in cases of suspected large bowel obstruction. Intravenous pyelography may be used to identify ureteral stones. All of these studies, however, have been supplanted in many centers by computed tomography (CT), which, although somewhat more expensive, yields considerably more information of practical importance.¹⁵ CT is quite useful in patients with abdominal pain who do not require emergency surgery, particularly in delineating the cause and suggesting a therapeutic strategy in patients with no prior history of abdominal disease.¹⁶ Arteriography may be useful in patients with suspected mesenteric ischemia, although CT angiography and magnetic resonance imaging are increasingly applied to this situation. Ultrasound examination of the right upper quadrant may reveal gallstones, but it is important to remember that ultrasonographic signs of acute cholecystitis may be no more accurate than clinical examination. Ultrasonography for lower abdominal pain may improve diagnostic accuracy beyond clinical impression alone but is highly experience and operator dependent.¹⁷ A guiding principle in ordering radiologic tests is that the result should substantially influence plans for further testing or therapy. Redundant tests should be avoided.

Diagnostic laparoscopy may be appropriate in certain circumstances, especially the evaluation of acute lower abdominal pain in females. This has become a more attractive option as techniques of therapeutic laparoscopy (e.g., appendectomy) have been refined.^{18–20} Nevertheless, laparoscopy requires a general anesthetic and should not be used without due consideration.

Conditions Mimicking the Acute Abdomen

A variety of nonsurgical conditions may be associated with acute abdominal pain, including a variety of cardiovascular, respiratory, metabolic, and toxic conditions. For example, myocardial ischemia may produce epigastric pain, nausea, and vomiting that simulate acute cholecystitis; conversely, and perhaps more frequently, acute cholecystitis is mistaken for pain of cardiac origin. Abdominal wall injury, radiculopathy, and rectus sheath hematoma (the latter particularly in patients on anticoagulant therapy) may cause acute abdominal pain. Abdominal pain and vomiting may accompany influenza. Diabetic ketoacidosis and, rarely, blood dyscrasias such as acute porphyria or sickle cell hemolytic crisis may produce severe abdominal pain. Urologic disorders such as pyelonephritis or obstruction of the ureter, renal pelvis, or bladder outlet may be mistaken for intra-abdominal pathology. Urinalysis and renal ultrasound may confirm the diagnosis. Testicular torsion can also be associated with severe abdominal pain.

Abdominal Pain in Special Circumstances

The pediatric population represents a particularly difficult subset in which to evaluate acute abdominal pain. In neonates and infants, congenital causes such as midgut volvulus or pyloric stenosis must be considered, and entities such as intussusception and Meckel diverticulitis are far more common than in adults. It may be impossible to obtain key historical information, and physical examination may be difficult.²¹ Evaluation of older children is generally easier. It should be noted that anorexia may be absent in children with appendicitis or other important abdominal pathology. Diarrhea as a manifestation of appendicitis is also frequent and may simulate acute infectious enterocolitis. Abdominal films may be more informative in pediatric than adult patients. In certain instances, it may be appropriate to consider whether child abuse has occurred.

The geriatric population can also present diagnostic difficulty, and if dementia is present, it may be impossible to elicit a meaningful history. In such patients, serious intra-abdominal pathology may present with few or subtle signs, and there may be only minimal tenderness on examination despite diffuse peritonitis. Laboratory values are frequently normal despite the presence of serious pathology in this population.²² The majority of geriatric patients evaluated in the emergency setting will be found to have significant disease requiring hospitalization.²³

2 Acute abdominal pain in immunosuppressed patients represents a particular diagnostic challenge, for example, in the setting of organ transplantation, immunosuppressive therapy for autoimmune disorders, chemotherapy, and acquired immunodeficiency syndrome (AIDS). Unusual infectious causes of acute abdominal pain, including cytomegalovirus (CMV), mycobacteria, protozoal species, and fungi, should be considered; these may affect the GI tract, gallbladder, liver, and pancreas. Perforation of the GI tract due to CMV, *Mycobacterium tuberculosis* or *Mycobacterium avium-intracellulare*, lymphoma, or Kaposi sarcoma or associated with corticosteroid use is seen in immunosuppressed patients. Acalculous cholecystitis should be considered in patients with AIDS and is often associated with *Cryptosporidia* or CMV. Splenic abscess due to *Candida* or *Salmonella* may be a cause of left upper quadrant pain. Neutropenic enterocolitis is a common cause of abdominal pain and fever in patients with bone marrow suppression due to chemotherapy. In the transplant population, acute graft-versus-host disease should be considered. Although abdominal pain in immunosuppressed patients is often treated nonoperatively, vigilance must be maintained lest serious surgical pathology be overlooked.

Acute abdominal pain after cardiac or major abdominal vascular surgery merits special mention because of the frequency of serious diagnoses that carry particularly high mortality in this setting. Mesenteric or segmental colonic ischemia is commonly reported, as are acute colitis and cholecystitis (often acalculous). Acute pancreatitis associated with extracorporeal cardiopulmonary bypass occurs in about 2% of cases.²⁴ Severe acute abdominal pain in hemodialysis patients is most commonly due to mesenteric ischemia.²⁵

The diagnosis of abdominal pain in patients with spinal cord injury is particularly challenging. Mortality in this setting is high (about 10%), usually due to delayed diagnosis.²⁶ Classical signs such as tenderness, guarding, and even fever are unreliable; more helpful are the presence of shoulder pain, abdominal distention, nausea, vomiting, and autonomic dysreflexia.²⁷

Finally, evaluation of abdominal pain occurring during pregnancy carries additional considerations.²⁸ Anatomic relationships may be distorted by the gravid uterus; in particular, the appendix is often displaced upward into the right upper quadrant. Nonsurgical causes of abdominal and pelvic pain are common. Interpretation of blood work should recognize physiologic alterations; leukocytosis is frequently present during normal pregnancy. Although one should not hesitate to obtain radiologic tests when essential, unnecessary exposure to x-rays must be avoided. Ultrasound is a particularly valuable diagnostic modality in these patients. More recently, magnetic resonance imaging has been demonstrated to be useful in the early identification of pregnant patients who are likely to require surgical intervention.²⁹

APPENDIX

The clinical entity of appendiceal inflammation followed by perforation, abscess formation, and peritonitis was first described in 1889 by Reginald Fitz.³⁰ Since that time, appendectomy has remained among the most common abdominal operations and, in fact, is the most common surgical procedure performed on an emergency basis in Western countries. Appendectomy remains the mainstay of treatment, but with the development of modern antibiotics and percutaneous drainage techniques, some cases are best managed nonoperatively. The morbidity and mortality associated with acute appendicitis has diminished over time, although because it usually affects young, healthy people, the overall effect on our workforce remains significant. When not treated appropriately, appendicitis remains a potentially lethal condition. A case in point is that of the famous magician, Harry Houdini, who would occasionally entertain by withstanding punches to the abdomen delivered by members of his audience. Unfortunately, Mr. Houdini once performed this “act” while suffering from an appendiceal abscess, only to die several days later from diffuse peritonitis and sepsis, the abscess having been ruptured from one of the assaults.³¹

Anatomy and Pathophysiology

The appendix is considered a vestigial organ with no known function in human beings. However, examination of the phylogenetic tree reveals that the appendix is absent from a number of carnivores, such as the dog, tiger, and lion, and, surprisingly, there is progressive development of the appendix in apes and as one ascends the primate scale.³² The appendix contains large amounts of lymphoid aggregates, similar to those within the Peyer patches of gut-associated lymphoid tissue. Lymphoid nodules containing both B and T cells within the lamina propria differentiate the appendix from the adjacent colon.³³ Because of this prominence of lymphoid tissue, some have hypothesized that the appendix may have an immune function similar to that of the thymus or bursa of Fabricius, although

no actual function has ever been documented. The appendiceal mucosa produces minimal amounts of fluid and digestive juices, suggesting that it has no important exocrine function. There have been some associations made between the lack of an appendix and various disease states (inflammatory bowel disease), but a causal relationship remains unproved.

The appendix develops as an antimesenteric outpouching from the cecum and is first delineated during the fifth month of gestation. The position of the appendix can vary greatly. In almost two thirds of the population, the appendix is located in a retrocecal position, whereas in others it is located over the pelvic brim, occasionally descending low down in the pelvis. When the appendix occupies an unusual location, the diagnosis of appendicitis may be more difficult and contribute to delays in either presentation and/or diagnosis. The three taenia coli of the ascending colon meet at the base of the appendix, with the anterior taenia serving as an important landmark. Following the taeniae can be a useful maneuver in identifying a difficult appendix at the time of operation. The appendix can vary in length from 2 to 20 cm, averaging approximately 9 cm. The blood supply of the appendix is from the appendicular artery, which is a branch of the ileocolic. Similarly, the lymphatic drainage follows that of the ileocolic nodes, and these are often hyperplastic in cases of acute appendicitis. The neural innervation of the appendix is derived from the autonomic nervous system. As with other visceral organs, there are no somatic pain fibers within the appendix. As such, early inflammation leads to poorly localizable pain and is referred to the periumbilical region because the autonomic nerves follow the midgut embryologic origin. As inflammation of appendicitis progresses, irritation of the surrounding parietal peritoneum results in the activation of somatic pain fibers and localization of symptoms and signs to the right lower quadrant.

In cross section, the appendix contains the same layers as those of the adjacent colon, including the mucosa, submucosa with prominent lymphoid tissue, circular and longitudinal muscle layers, and overlying serosa. Neurosecretory cells are located within the subepithelial layer and are the presumed source of carcinoid tumors, which are often found within the appendix.

3 The etiology of appendicitis remains somewhat unclear. In most patients, there is probably luminal obstruction that leads to bacterial overgrowth and increased luminal pressure, leading to obstruction of venous outflow and then arterial inflow, resulting in gangrene and eventual perforation. The cause for the luminal obstruction that initiates the process of appendicitis is postulated to involve lymphoid hyperplasia, a condition that is especially common in the teenage years, which correlates with the high incidence of appendicitis in this age group. It is felt that either viral or bacterial infections such as *Shigella*, *Salmonella*, infectious mononucleosis, and so forth can precede the episode of appendicitis, presumably by initiating the lymphoid hyperplasia and subsequent luminal obstruction.

In addition to lymphoid hyperplasia, fecaliths can also lead to appendiceal obstruction and subsequent appendicitis. It is thought that approximately 30% of cases of acute appendicitis in adults are linked to fecaliths. Fecaliths are thought to occur following entrapment of vegetable matter with subsequent mucus deposition and eventual calcification. The “obstructive” model for appendicitis does not appear to explain the etiology in all cases, however, because some patients with appendicitis appear to have a patent lumen by radiologic, gross, and histologic examination. The pathophysiology of these cases remains unclear.

Diagnosis

Early diagnosis remains the most important clinical goal in patients with suspected appendicitis. Although mortality rates in modern series are well under 1%,^{34,35} the morbidity of

TABLE 72.8 **DIAGNOSIS****TYPICAL SEQUENCE OF SYMPTOMS AND SIGNS OF ACUTE APPENDICITIS**

Periumbilical pain—vague, visceral, poorly localized
 Anorexia, nausea, and/or vomiting
 Right lower quadrant pain and tenderness—localized
 Fever
 Leukocytosis

perforated appendicitis is much higher than in nonperforated cases and is related to increased rates of wound infection, intra-abdominal abscess formation, lengths of hospital stay, and delayed return to full activity.³⁶

By a thorough history and physical examination, experienced clinicians can accurately diagnose acute appendicitis in the majority of cases.⁴ A typical presentation (Table 72.8) is that of vague periumbilical pain (sometimes located more superiorly in the epigastric region) followed by anorexia, nausea, or even frank vomiting. When vomiting occurs in appendicitis, it is usually of a limited nature, as opposed to patients with viral gastroenteritis, who generally have more severe vomiting. The pain then shifts to the right lower quadrant region as the inflammatory process progresses and involves the localized overlying peritoneum. Eventually, fever ensues and this is followed by the development of leukocytosis. These clinical features are not entirely reliable, however. For example, not all patients will complain of anorexia, so the fact that a given patient expresses hunger should not necessarily deter one from surgical intervention for presumed acute appendicitis. Occasionally, patients will complain of urinary symptoms, perhaps because of some inflammation adjacent to the ureter and/or bladder. Microscopic hematuria is quite common, and the clinician should not mistake the primary problem as residing in the urinary tract. Intestinal function is usually unaffected in appendicitis, but some patients will note diarrhea, perhaps related to the inflammation adjacent to the rectum and/or colon. Appendicitis can also be associated with adynamic ileus, leading to the complaint of constipation.

Physical examination is generally the most reliable indicator of appendicitis. Aside from the young child, very elderly, or otherwise neurologically impaired, patients with appendicitis will have at least some degree of tenderness on palpation of the abdomen. In cases of an appendix located entirely in the pelvis, the tenderness on abdominal examination may be minimal, but on rectal examination the tenderness will be evident as the pelvic peritoneum is manipulated. Pelvic examination with cervical motion will also manipulate the pelvic peritoneum and elicit tenderness when there is an inflamed appendix in that region. Therefore, the finding of cervical motion

tenderness does not necessarily indicate gynecologic pathology but rather is a nonspecific sign of inflammation in the pelvis.

Peritoneal irritation can be elicited on physical examination with the findings of percussion and/or rebound tenderness. Any movement including coughing (Dunphy sign) may cause increased pain. The most reliable indicator of peritoneal irritation, however, is involuntary guarding, a reflex contraction of the abdominal wall musculature overlying the inflamed peritoneum. The involuntary nature of this response is less dependent on the individual variation seen in response to external stimuli. Other physical signs (Table 72.9) associated with appendicitis include the occurrence of pain in the right lower quadrant during palpation of the left lower quadrant (Rovsing sign), pain on internal rotation of the hip (obturator sign, suggesting a pelvic appendix), and pain on right hip extension (iliopsoas sign, typical of a retrocecal appendix).

In addition to the history and physical examination, a white blood cell count is usually obtained and in most patients will be elevated, although it may be in the normal range during the early stages. A very high white blood cell count ($>20,000$ white blood cells per mL) suggests complicated appendicitis with either gangrene or perforation. A urinalysis can also be helpful to rule out pyelonephritis or nephrolithiasis. However, in patients with pyelonephritis, the fever and white blood cell count will generally be much higher than that seen in appendicitis, symptoms of dysuria will be present, and the tenderness is centered more in the flank or costovertebral angle region. Minimal pyuria, frequently seen in elderly women, should not deter one from the correct diagnosis of appendicitis. Although microscopic hematuria is common in appendicitis, gross hematuria is uncommon and may indicate the presence of a kidney stone. As a kidney stone passes down the urinary tract through the distal ureter, pain can often be referred to the right lower quadrant region and occasionally down into the testicle. The pain is quite severe and entirely visceral in nature. Therefore, the signs of peritoneal irritation should not exist in the patient with nephrolithiasis. Other blood tests are generally not helpful nor indicated in the patient with suspected appendicitis.

Plain abdominal radiographs are of little use in the patient with suspected appendicitis. Occasionally, a calcified appendicolith may be evident, but this is a rare event ($\sim 17\%$) and, in any case, does not really establish the diagnosis even if present.³⁷ Plain abdominal films can show indications of mechanical bowel obstruction or the presence of free intraperitoneal air, but such conditions should rarely be confused with appendicitis.

Given the inherent limitations in establishing the diagnosis of acute appendicitis and a concern that a delay may result in perforation with increased associated morbidity and possible mortality, a false appendectomy rate of approximately 20% has been considered acceptable. Certainly, if the negative appendectomy rate were much higher, one could question the diagnostic acumen and experience of the clinicians involved. On the other hand, in some centers a negative appendectomy rate of less than 10% has been accomplished,³⁵ and it is likely

TABLE 72.9 **DIAGNOSIS****SIGNS ON PHYSICAL EXAMINATION SUGGESTIVE OF ACUTE APPENDICITIS**

SIGN	WHAT IT INDICATES	DESCRIPTION
Dunphy	Inflammation involving the partial peritoneum	Increased pain with coughing or other movement
Rovsing	Localized peritoneal inflammation in the right lower quadrant	Lower left quadrant palpation induces right lower quadrant pain
Obturator	Pelvic appendicitis	Pain on internal rotation of the right hip
Iliopsoas	Retrocecal appendicitis	Pain on extension of right hip

that the addition of newer imaging modalities to evaluate acute abdominal pain has improved accuracy to the point where the modern standard of care should be substantially better than the historical target of 20%. Clearly, clinical experience and expertise is an important factor in establishing a correct diagnosis. In addition, in-hospital observation has been touted as an excellent way to closely follow patients and quickly intervene for worsening abdominal pain, peritoneal irritation, or fever. Using this approach, White et al.³⁸ reported a negative appendectomy rate of 6%. Cost-effectiveness of in-hospital observation strategies has not been determined. Of course, with a low negative appendectomy rate, one must ensure that there are few patients who develop perforated appendicitis while being observed in the hospital or after being sent home from an emergency room visit.

- 4 To improve diagnostic accuracy in patients with suspected appendicitis, other radiologic tests have been used. Ultrasonography has been reported to aid in the diagnosis of acute appendicitis^{39,40} by the demonstration of a so-called target lesion (i.e., a thick-walled, noncompressible, luminal structure in the right lower quadrant). In more advanced cases, peritoneal fluid and even a frank abscess may be found. However, a number of large series^{41,42} have shown ultrasound to be unreliable, both in terms of sensitivity and specificity, such that it probably should not be used in the routine diagnosis of acute appendicitis. Ultrasound may be helpful if it suggests a diagnosis other than appendicitis, especially gynecologic pathology in women of menstrual age. It must be cautioned, however, that simple cysts of the ovary are common and usually nonpathologic. As such, the presence of an ovarian cyst does not weigh against the diagnosis of acute appendicitis. On the other hand, if ultrasonographic signs of a tubo-ovarian abscess, ovarian torsion, or even rare complications related to uterine fibroids are present, then the diagnosis of appendicitis may be excluded (Fig. 72.1).
- 5 More recently, abdominal and pelvic CT scan has been used in the setting of suspected acute appendicitis^{43,44} and appears to be more accurate than ultrasound.⁴⁵ Rao et al.⁴⁶ suggested that CT scan can lead to significant cost savings, because a normal study virtually excludes the diagnosis and obviates the need (and costs) of in-hospital observation. CT scan should include thin cuts through the area of the appendix and the use of rectal contrast to distend the cecum and make the adjacent inflammatory changes more evident. The role of CT scan in the diagnosis of appendicitis, however, remains controversial, because in most patients an accurate diagnosis

FIGURE 72.1. Acute appendicitis in a 53-year-old woman with fever and right lower quadrant pain and tenderness. Note the thick-walled, fluid-filled appendix with surrounding inflammation. A gangrenous appendix was found at operation.

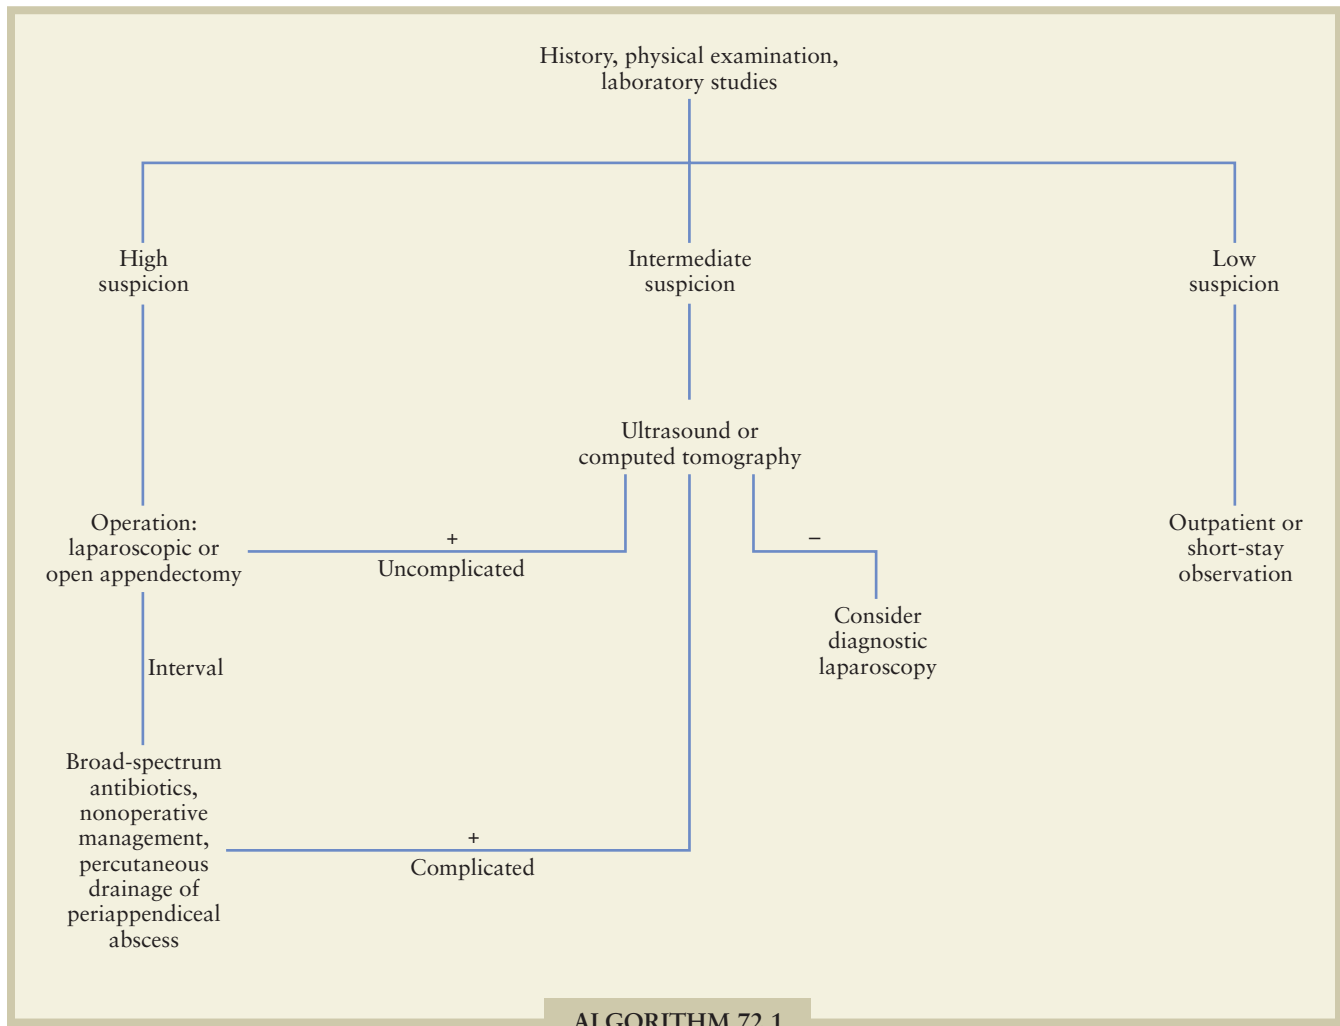

can be reached simply by history and physical examination. In the setting of early acute appendicitis, pathologic changes in the gross appearance of the appendix may be minimal even with direct observation at the time of surgery and may well be missed by all radiologic techniques. One advantage of CT scan, similar to that of ultrasound, may be the detection of pathology other than acute appendicitis.⁴⁷

Barium enema has been used in the past in an attempt to diagnose appendicitis.⁴⁸ Failure to fill the appendix has been associated with appendicitis, but up to 20% of normal appendices do not fill and therefore the diagnosis cannot be accurately established using this criterion. Occasionally, in more advanced cases with abscess formation, a mass effect will be seen compressing the adjacent cecum. However, such a finding would probably be better visualized by CT, which also provides the opportunity for percutaneous drainage. On occasion, barium enema can detect a colonic mucosal lesion such as a neoplasm or terminal ileal abnormalities related to Crohn disease, thereby establishing a diagnosis other than appendicitis. Overall, however, barium enema has little role in the modern management of suspected acute appendicitis.

Treatment

The standard treatment for suspected appendicitis is appendectomy via a right lower quadrant incision (Algorithm 72.1). The classical McBurney incision employs an oblique approach, incising each of the three abdominal wall muscle layers lateral to the rectus sheath. Ideally, the incision should follow Langer skin lines to provide an optimal cosmetic result. The aponeurosis overlying the external oblique can be sharply incised, and the remaining muscle layers split by retraction. The peritoneum is opened, the appendix is identified, and its blood supply is then ligated, usually from tip to base. Depending on the degree of surrounding inflammation and the length of time of the illness, mobilization of the appendix may be difficult and may require division of the lateral attachments of the cecum. The appendix itself is usually ligated with an absorbable suture and then inverted into the cecal wall through the use of a pursestring or Z-stitch. Inversion of the appendiceal stump has been advocated to prevent leakage and fistulization, but numerous reports have shown no difference in complication rates between inversion and simple ligation of the appendiceal stump.⁴⁹ Following appendectomy, irrigation of the peritoneal cavity should be carried out and then the peritoneum and muscles should be closed in layered fashion, usually with absorbable sutures. The skin incision can generally be safely closed, although in grossly contaminated cases, one may consider delayed primary closure or simply healing by secondary intention. However, based on a large meta-analysis, it appears that there is little if any role for delayed primary closure.⁵⁰ Intraperitoneal drains have not proven to be useful even in cases of perforated appendicitis.⁵¹ Although the effectiveness of appendectomy for acute appendicitis is rarely questioned, the supporting evidence is surprisingly meager. Scattered reports have suggested the possibility of nonoperative (antibiotic alone) therapy for selected cases of early acute appendicitis,⁵² although this approach remains anathema in classical surgical teaching.

If a normal appendix is found at the time of laparotomy, other causes for the abdominal pain should be sought. The cecum and proximal ascending colon should be examined for right-sided diverticulitis, neoplasms, or other pathology. The terminal ileum should be examined for Crohn disease or acute ileitis, and the ileum should be inspected for at least 2 feet proximal to the ileocecal valve for the presence of a Meckel diverticulum. If Crohn disease is encountered, the appendix may be safely removed as long as the cecum and particularly the base of the appendix are not involved with the inflammatory process. If uncomplicated Crohn inflammation is detected,

ALGORITHM 72.1. Management of suspected appendicitis.

ileal resection is not indicated, but in the case of a gross perforation or advanced Crohn disease with obstruction, resection should be performed. Occasionally, sigmoid diverticulitis may be mistaken for acute appendicitis, especially when a redundant sigmoid colon reaches the right side of the abdomen. Finally, the fallopian tubes, ovaries, and uterus should be carefully examined in female patients.

Laparoscopy. The role of laparoscopy and laparoscopic appendectomy has expanded greatly in recent years. Many surgeons advocate diagnostic laparoscopy especially for young women. Laparoscopy allows easy visualization of the pelvic organs as well as the appendix and can establish the diagnosis of appendicitis or other processes.^{53,54} Laparoscopic appendectomy has gained substantial popularity. Generally, the laparoscope is inserted through a periumbilical incision and then additional trocars are placed, one in the right lower quadrant to grasp the appendix and another on the left side to perform dissection, ligation, and, ultimately, removal of the appendix. Endoscopic stapling devices have simplified transection and closure of the appendiceal stump at its base as well as hemostatic division of the mesoappendix. Numerous series have compared laparoscopic to open appendectomy.^{55,56} As in many other minimally invasive procedures, a learning curve clearly exists and may explain the longer operative times in initial reports. With experience, however, operative times for the

laparoscopic approach probably equal and may be superior to open appendectomy. Complication rates appear to be low and are probably no different between the laparoscopic and open techniques, although postoperative infections may be less common with laparoscopy. Laparoscopy may also be of benefit in regard to hospital stay and overall recovery. Most reports in the literature indicate that length of stay is significantly shorter using the laparoscopic route, as is narcotic usage and other parameters associated with postoperative morbidity.⁵⁷ In a large retrospective series,³⁵ laparoscopic appendectomy was found to be particularly valuable in cases of gangrenous and/or perforated appendicitis. For simple acute appendicitis, hospital stay and recovery periods were short, regardless of operative approach. However, in the more advanced cases, laparoscopy was associated with shorter hospital stays and faster recovery. Based on a large Cochrane review, the most consistent differences in laparoscopic versus open appendectomy are that laparoscopic appendectomy is associated with a reduction in wound infections (by approximately one half) and intra-abdominal abscesses.⁵⁸

Appendiceal Mass

Some patients with appendicitis will present at a relatively late stage in their illness (greater than about 5 days). Although in

FIGURE 72.2. A 23-year-old man with 2 weeks of right lower quadrant pain, fever, and leukocytosis. Note the large periappendiceal abscess containing gas. The patient was successfully treated with percutaneous drainage and antibiotics.

most cases acute appendicitis progresses to perforation and diffuse peritonitis within the first few days of the illness, virtually forcing the patient to seek medical attention, occasionally an appendiceal perforation is contained by surrounding structures including the omentum and adjacent bowel. Instead of developing diffuse peritonitis, these patients develop a localized inflammatory mass or phlegmon with or without a discrete abscess. The associated pain and other systemic signs are limited by this process, which may explain the delayed presentation. Such patients usually have right lower quadrant abdominal pain, tenderness on examination, and a palpable mass or fullness, although overlying guarding of the abdominal wall musculature may obscure the mass. The key diagnostic feature to be recognized in these patients is the length of time of the illness, because a walled-off appendiceal mass generally requires a minimum of 5 days to form. In such cases, CT scan may establish the diagnosis and allow for percutaneous abscess drainage (Fig. 72.2). In the acute setting, these patients are best treated nonoperatively, because, although the appendix can be removed, there is added risk of injury to adjacent structures, including the small bowel. The overall morbidity in these patients appears to be decreased by the nonoperative approach, with or without percutaneous drainage.⁵⁹ Intravenous antibiotics are administered initially, and most of these patients will respond within a 24- to 48-hour period with a decrease in pain and fever. The patients can then be safely discharged on a course of oral antibiotics and a normal diet. The appendiceal inflammation generally subsides within 1 to 2 weeks. Antibiotics should continue for a total of approximately 2 weeks.

It should be noted that patients who have undergone percutaneous or open drainage of a periappendiceal abscess rarely develop fistulization from the cecum. Similarly, patients with perforated appendicitis almost always have pus within the peritoneal cavity, rather than actual enteric contents. These observations support the concept that most cases of appendicitis are associated with some obstruction of the lumen of the appendix.

Following the successful nonoperative treatment of an appendiceal mass, consideration should be given to interval appendectomy. A period of approximately 8 to 12 weeks will allow resolution of the inflammatory changes surrounding the appendix. Removal of the appendix after such a time period is generally safe and simple, although in rare circumstances, a significant amount of periappendiceal scar tissue and inflammation will persist. Whether or not to perform an interval appendectomy remains controversial. A number of investigators have examined the incidence of recurrent appendicitis following presentation with an appendiceal mass and successful nonoperative treatment. Based on a recurrence rate of approximately

10% (6-month to 13-year follow-up), Ein and Shandling⁶⁰ suggested that interval appendectomy is not indicated in all patients. The incidence of recurrence may be higher in younger patients and therefore the decision to perform the interval appendectomy should probably be individualized by patient age. One must remember, however, especially in the elderly patient, that the original diagnosis of appendicitis may have been mistaken and it is important to rule out a cecal neoplasm in such patients if interval appendectomy is not performed.

More recently, interval laparoscopic appendectomy has been shown to be a safe and simple procedure with a high degree of patient acceptance. The operation can generally be performed on an outpatient basis with minimal morbidity.⁶¹ Laparoscopy, therefore, may have shifted the risk-benefit ratio in favor of interval appendectomy.

Antibiotic Therapy

Patients with acute appendicitis should be treated with perioperative broad-spectrum antibiotics directed against colonic flora, including gram-positive, gram-negative, and anaerobic organisms. Peritoneal cultures are generally not clinically helpful in the selection of the type of antibiotics.⁶² The optimal length of antibiotic therapy is not known. In simple cases of acute appendicitis, 24 hours or less is generally sufficient. However, in cases of perforated appendicitis, longer courses of antibiotics are generally used, approximately 5 to 7 days.

Recurrent Appendicitis

Rarely, a patient will present with recurrent episodes of presumed acute appendicitis. At each presentation, spontaneous resolution may occur, with or without the use of antibiotics. Such patients may eventually come to appendectomy, and it is only in retrospect that the previous episodes are recognized to have been due to acute appendicitis. Recurrent appendicitis is occasionally termed *chronic appendicitis*, but this is probably a misnomer because the appendix is almost certainly uninfamed in the interval between episodes. Some patients will present in the outpatient setting for evaluation of chronic or intermittent right lower quadrant pain, raising the question of recurrent and/or chronic appendicitis. This difficult scenario requires clinical expertise to rule out etiologies other than appendicitis and to determine whether surgery is indicated. In general, discrete episodes of right lower quadrant pain, especially associated with fever and/or leukocytosis, are the best indicators of pathology within the appendix, and these patients respond most favorably to appendectomy. In contrast, patients with chronic right lower quadrant pain recurring frequently or even daily, in the absence of associated fever, are unlikely to benefit from appendectomy.

Appendicitis in Special Patient Populations

- 8 Children.** The diagnosis of acute appendicitis is generally more difficult in young children compared to adults.²¹ An accurate history may be difficult to obtain, and some of the signs of appendicitis such as nausea, vomiting, abdominal pain, and tenderness are often seen with other, extra-abdominal processes (e.g., pneumonia, meningitis, otitis media). The difficulty in establishing an accurate diagnosis in children is the presumed reason for a higher perforation rate in this population, reported to be as high as 50%. As such, the use of radiologic studies such as CT scan may be of particular benefit in children with suspected appendicitis. A negative appendectomy rate as low as 4% was reported with the routine use of ultrasound or CT.⁶³ However, this has not been the experience of all groups, and there is concern about the potential increase

in lifetime risk of cancer in children who have undergone radiation exposure due to a single CT scan.⁶⁴

- 9 Elderly Patients.** As in a number of other disease entities, elderly patients tend to present later in their course of appendicitis and clearly have higher associated rates of morbidity and mortality.⁶⁵ Perforation rates in elderly patients with appendicitis are quite high (>50%). Elderly patients tend to have less subjective pain, have decreased findings of peritonitis on examination, and may have a delayed leukocytosis. Therefore, the index of suspicion for an intra-abdominal inflammatory/infectious process, including acute appendicitis, must be higher in elderly patients compared to the general population.

Immunocompromised Patients. The patient with an impaired immune system who complains of abdominal pain represents a particularly challenging problem for the clinician.⁶⁶ Patients with AIDS or those who have been exposed to high-dose chemotherapy are susceptible to specific disease entities, including CMV-related bowel perforations and typhlitis (neutropenic colitis). Because these disease processes most commonly affect the terminal ileum and cecum, they can often be confused with acute appendicitis. CT scan can be particularly helpful in this setting in order to establish a definitive diagnosis, although in some cases the findings of pericecal inflammation are nonspecific. In general, regardless of the underlying disease process, surgery is indicated in the patient with spreading peritonitis or with systemic signs of sepsis related to an intra-abdominal infection.

- 10 Pregnancy.** Appendicitis is the most frequent nonobstetric indication for laparotomy during pregnancy. Pregnant women will often present with abdominal pain, particularly in the lower abdomen, raising the suspicion of appendicitis. A diagnosis can be difficult to establish, especially because abdominal pain, nausea, and vomiting are quite common in early pregnancy. The white blood cell count is slightly elevated in normal pregnancy, adding further difficulties to establishing the diagnosis of appendicitis. In addition, as the uterus enlarges, the anatomic location of the appendix will be shifted upward, and the uterus may cover the appendix, thereby diminishing the signs of peritoneal inflammation. Because of these complicating factors, the perforation rate of appendicitis during pregnancy is probably higher than in the general population.^{67,68} Unfortunately, perforated appendicitis is also associated with high fetal mortality (>30%), whereas simple acute appendicitis has a risk of fetal loss in the range of 10% and poses negligible risk to the mother. As such, it is best to be aggressive in recommending surgical exploration in pregnant women with suspected appendicitis, especially because a “negative” appendectomy is well tolerated with minimal morbidity to mother and fetus. Numerous reports have indicated the safety of laparoscopy in the setting of pregnancy.⁶⁹ However, in the third trimester, the enlarged uterus may limit the exposure and preclude a laparoscopic approach.

Appendiceal Neoplasms

Approximately 1% of all appendectomy specimens will contain a neoplasm.⁷⁰ The most common tumor is the carcinoid. Rare tumors of the appendix include benign and malignant mucocoeles, adenocarcinoma, and adenocarcinoids.

Carcinoids. Approximately one third to two thirds of all appendiceal neoplasms are carcinoids, tumors of neural crest origin and derived from enteroendocrine cells. Of all carcinoid tumors within the GI tract, approximately half arise within the appendix. Carcinoid tumors of the appendix are usually found incidentally on pathologic examination of the inflamed appendix. These tumors have a characteristic firm yellow appear-

ance and are often associated with a surrounding desmoplastic reaction. In regard to treatment and prognosis, the key feature is the size of the tumor. Most carcinoids are less than 1.5 cm in diameter, and these tumors are adequately treated by simple appendectomy. The chance of lymphatic or distant metastasis is essentially zero and the prognosis for cure should be excellent. On the other hand, tumors that are 2 cm in size or greater begin to show metastatic potential. In such cases, a formal right hemicolectomy is generally indicated, and the prognosis remains quite good. Other indications for right colectomy include high-grade malignant lesions with a high mitotic index, mesoappendiceal invasion, tumors located at the base of the appendix with positive margins, and goblet cell adenocarcinoid tumors.⁷¹ Rarely, appendiceal carcinoids are associated with liver metastases, and in these cases the carcinoid syndrome may be present. The number and location of liver lesions, as well as the associated symptoms, would dictate treatment in these cases.^{72,73}

Mucocoeles. Mucocoeles of the appendix can be due to both benign and malignant disease, either cystadenomas or cystadenocarcinomas. These tumors obstruct the appendiceal lumen, leading to a large mucin-filled structure, often with calcification in the wall. Such tumors can generally be diagnosed by CT scan.

Appendectomy is curative for benign cystadenomas, even if rupture has occurred with mucinous ascites. However, with rupture of a cystadenocarcinoma, peritoneal tumor implantation can occur, leading to mucin secretion and a condition known as pseudomyxoma peritonei. The presence of mucin-secreting cellular elements in the peritoneal cavity distinguishes this malignant condition from the benign cystadenoma rupture with simple mucinous ascites. There is no effective treatment for pseudomyxoma peritonei, and these patients can develop secondary complications including bowel obstruction and perforation. The neoplastic process tends to be fairly indolent (5-year 50% survival), and repeated debulking procedures may be indicated.⁷⁴

Adenocarcinoma. Adenocarcinoma of the appendix is extremely rare and like other appendiceal neoplasms is generally found unexpectedly at the time of appendectomy. Unfortunately, up to one half of the patients have metastatic disease at the time of diagnosis, usually with peritoneal spread presumably from rupture of the associated inflammatory process. Staging and treatment for appendiceal adenocarcinoma is similar to that for the more common colon carcinoma. Early lesions confined to the mucosa or submucosa (Dukes A) may be treated by simple appendectomy, as long as clear surgical margins are present. Dukes B and C lesions require formal right hemicolectomy, with adjuvant therapy indicated similar to colon carcinoma. Interestingly, appendiceal adenocarcinomas are associated with secondary tumors in up to 35% of patients, most often involving other areas of the GI tract.⁷⁵

CHAPTER 73 ■ THE SPLEEN

DOUGLAS L. FRAKER

KEY POINTS

- 1 The spleen relates to the diaphragm both superiorly and laterally, and it generally spans the 9th, 10th, and 11th ribs along the left mid to posterior axillary line.
- 2 Accessory spleens are small nodules of splenic tissue that are completely separate from the main body of the spleen. They commonly range in size from 0.5 cm up to 3 to 4 cm.
- 3 The primary hematologic function of the spleen is removal of senescent erythrocytes or remodeling of abnormal red blood cells, and the recycling of iron by splenic macrophages.
- 4 The immunologic function of the spleen is to generate an immune response to antigens that are identified and cleared from the blood system.
- 5 Typically, encapsulated organisms cause the postsplenectomy sepsis-related infection.
- 6 The spleen is the most common intra-abdominal organ injured by blunt trauma in the United States.
- 7 The pathophysiology of ITP is development of an IgG antibody to a platelet antigen. In patients who have not achieved a sustained remission with medical therapy, which is most patients with chronic ITP, an elective splenectomy is recommended.
- 8 Hypersplenism is a physical enlargement of the spleen that can occur due to neoplastic disorders, hematopoietic disorders of the bone marrow, and metabolic or storage disorders. In the neoplastic disorders, the spleen is infiltrated and enlarged by leukemia or lymphoma cells.

The spleen has been a mysterious organ throughout surgical and medical history with a clear understanding and appreciation of its function only in the latter half of the 20th century. The reasons for this paucity of knowledge on the spleen are multifactorial. The spleen has no obvious function that can be discerned from its anatomic structures or features; there are no clear relationships of gross pathology of the spleen to many of the diseases for which it is important; and even in present time it is difficult to obtain a biopsy of the spleen, thereby limiting the amount of tissue available for pathologic study. The diseases (other than trauma) in which the spleen has importance are generally of a hematologic or immunologic nature. Understanding of the normal physiology and subsequent pathophysiology of the spleen is important for surgical decision making regarding when to recommend splenectomy and whether a partial splenectomy is possible. The only surgical procedure for most of the history of medicine applied to the spleen was splenectomy. Current variations on that procedure include laparoscopic splenectomy, partial splenectomy, and other splenic preservation procedures. The history of splenic surgery, the anatomy and physiology, and the disease processes as well as operative techniques involving the spleen will be reviewed.

HISTORY

The spleen has had a colorful history based on the function ascribed to this organ by many of the prominent scientists throughout the ages (Table 73.1).¹ Even the origin of the English term “spleen” is unclear. It is believed to come from the Greek “splen,” which may have been derived from the Greek word “splanknon” meaning a viscus or the Greek word “spaw,” which means to draw.¹ The dark purple-red color led ancients to believe that the spleen may draw spoiled or bad parts of the blood to itself, which presages one of the major roles of the spleen as a filtration device for senescent red blood cells. In ancient Greece, the spleen was believed to be the source of black bile, which was one of the four cardinal humors related to melancholy.² However, ancient authors wrote in the Talmud that the spleen was the seat for laughter and removal of the spleen

would limit mirth in that person.² The spleen was thought to be a source of discomfort sometimes felt as “a stitch in the side” for athletes and that by removal or ablation of the spleen an individual would run faster. Reports of the earliest procedures on the spleen indicate that runners in ancient Greece may have had their spleens ablated in an effort to improve their performance. This hypothesis was studied in an experimental model almost 2,000 years later at Johns Hopkins in which splenectomized mice versus control mice were evaluated for their ability to run a race and the splenectomized mice were reported to be faster.²

During the Renaissance, scientists questioned the functional roles ascribed to the spleen. In the early 16th century, Princelsus rejected the black bile theory and questioned whether the spleen had any meaningful role at all. Zaccarella, one of Princelsus’ students, reportedly performed the first splenectomy in 1549 in Palermo, Italy, successfully removing the large spleen of a 24-year-old woman (Table 73.1).² This organ was reportedly displayed in the town square after this landmark but unsubstantiated procedure. Versalius during that same era performed splenectomy in mice and other animals and determined that the spleen was not essential to life as there was no clear difference following removal. The first authenticated splenectomy was performed in Germany in 1826 by Carl Frederick Quittenbaum in a patient with secondary hypersplenism due to cirrhosis. This high-risk patient succumbed 6 hours after the procedure. The first successful operation in which the patient survived was performed by Jules Péan in France in 1865 for a large splenic cyst. This patient was operated on for what was thought to be an ovarian cystic mass, but it was found to be arising from the inferior portion of the spleen and required splenectomy for removal. In this early period of splenic surgery, there was much pessimism due to the high operative mortality rate primarily from hemorrhage. A collective series published in 1877 reported 50 splenectomies with 70% mortality. By 1900, Bessel-Hagen reported 360 splenectomies with 40% mortality. An in-depth discussion of the spleen in literature, art, and history was recently published by Morgenstern (3).

The 20th century brought technical advances in terms of hemostasis and blood transfusion as well as an understanding of the pathophysiology of splenic function.⁴ The spleen was

TABLE 73.1**HISTORICAL MILESTONES IN SURGERY OF THE SPLEEN**

1549	First reported splenectomy by Zaccarella in Italy
1826	First documented splenectomy by Quitterbaum in Germany
1865	First successful splenectomy by Péan in France

1911	Elective splenectomy for autoimmune hemolytic anemia
1916	Elective splenectomy for immune thrombocytopenia purpura
1952	First report of overwhelming postsplenectomy sepsis
1962	First report of splenic salvage procedure for trauma
1991	Laparoscopic splenectomy

identified as the site of red cell destruction in autoimmune hemolytic anemia by Micheli in 1911. In 1916, Paul Kaznelson, a Czech medical student, postulated that the removal of the spleen in patients with idiopathic thrombocytopenic purpura would be of benefit, and he reported the successful treatment of a patient with that disease by splenectomy. Throughout the 20th century, as understanding of the pathophysiology of hematologic and immune disorders associated with the spleen increased, the roles for splenectomy that are pertinent to modern-day practice became more clear.

EMBRYOLOGY AND ANATOMY

The spleen develops from the mesoderm as an outpouching from the mesogastrium during the 5th week of gestation.⁴⁻⁶ Natural rotation of the gut during subsequent development places the spleen in its typical position in the left upper quad-

1 rant of the abdomen (Fig. 73.1). In that location, the spleen relates to the diaphragm both superiorly and laterally, and it generally spans the 9th, 10th, and 11th ribs along the left mid to posterior axillary line. The ventral surface of the spleen abuts the greater curvature of the stomach and the tail of the pancreas. The tail of the pancreas touches the splenic capsule in 30% of cases and is 1 cm away in 73% of cases. The inferior pole relates to the left kidney posteriorly and the splenic flexure of the colon anteriorly.

The normal size of the spleen is approximately $13 \times 7 \times 4$ cm.⁵ The typical weight of a spleen in a young adult is 150 to 200 g, and this decreases to approximately 100 g in the elderly population (Fig. 73.2).^{7,8} If the spleen doubles in size to the range of 300–400 grams, it may project below the costal margin allowing palpation of the spleen tip on abdominal exam on deep inspiration.⁹ The splenic weight defining massive splenomegaly has been arbitrarily set at 1,500 g. There is sometimes a significant cleft in the capsule of the spleen that may be confused with splenic disruption on CT scan obtained for trauma.

The vascular anatomy of the spleen is rather straightforward.¹⁰ The splenic artery is one of the three major trunks of the celiac axis, along with the left gastric artery and common hepatic artery (Fig. 73.3). This artery has a characteristic appearance on celiac arteriograms as a serpentine vessel with loops extending both superiorly and inferiorly. There are several small pancreatic branches that supply blood to the body and tail of the pancreas along its length. The first major splenic branch occurs approximately 2 to 3 cm from the hilum, and it is called the superior polar artery. The main artery then divides into three to five segmental branches that enter along the trabecula of the spleen. Additional blood supply to the spleen comes from the left gastroepiploic artery via the short gastric vessels. When the spleen is massively enlarged, it may have direct vessels that are parasitized from the omentum, diaphragm, or the mesentery of the splenic flexure of the colon. The splenic artery generally travels outside the parenchyma of the pancreas just at the superior border although loops that go inferiorly may be completely covered by the posterior surface of the pancreas whereas superior loops may be well away from the pancreatic surface. These curves that are

FIGURE 73.1. Anatomic relation of the spleen to the liver, diaphragm, pancreas, colon, and kidney. The stomach is sectioned to illustrate the anatomic relation in situ.

Visceral surface of spleen

FIGURE 73.2. A: The lateral or diaphragmatic surface of the spleen, showing the lobulated edge and the glistening capsule. B: The hilar surface of the spleen, showing the ligatures on the cephalad short gastric vessels and the caudal hilar vessels.

FIGURE 73.3. The arterial blood flow to the spleen is derived from the splenic artery, the left gastroepiploic artery, and the short gastric arteries (vasa brevia). The venous drainage into this portal vein is also shown.

FIGURE 73.4. The relations of the spleen to the abdominal and retroperitoneal viscera are seen in a cross section of the left-facing torso.

exposed along the cranial surface of the pancreas are the optimal location to place a ligature for control of the splenic artery during procedures in which there is significant thrombocytopenia or for enlarged spleens. These are generally areas that have few pancreatic branches and avoid proximity to the splenic vein.

The splenic vein is formed by segmental venous branches that leave the trabecula and coalesce into the main splenic vein in the hilum of the spleen (Fig. 73.3). The splenic vein is intimately associated with the posterior surface of the tail and body of the pancreas from the hilum of the spleen to its junction with the superior mesenteric vein, where they form the portal vein. The inferior mesenteric vein may join the splenic vein directly at several areas along its course or may come together right at the junction of the superior mesenteric vein. There are several pancreatic branches that directly enter the splenic vein. The blood flow to the spleen in the typical adult is estimated to be 200 to 300 mL/minute, or approximately 5% of the cardiac output.¹⁰

The lymph node drainage generally follows the vasculature. The primary lymph nodes are located in the hilum of the spleen, along the splenic artery at the superior border of the pancreas, and along the short gastric vessels.

There are several ligaments that maintain the spleen in its fixed position in the left upper quadrant (Fig. 73.4).⁶ Three of these ligaments are virtually always present (except in the condition of the wandering spleen),¹¹ and two may be present to variable extents, depending on the individual patient and the disease process. The first ligament that is constant is the splenogastrotic ligament, which is a left-sided superior extension of the greater omentum along the proximal greater curvature of the stomach. Within this area supplied by the left gastroepiploic vessels are short gastric vessels that branch to the upper pole of the spleen and often provide the upper two thirds of the spleen with alternative blood supply. The second and very important ligament is the splenorenal ligament that runs parallel to the posterolateral border of the spleen and attaches this to the superior pole of the Gerota fascia developing the left kidney. This ligament is divided when mobilizing the spleen during splenectomy and allows reflection of the spleen with or without the tail of the pancreas. The splenocolic ligament is short and may be avascular or have small blood vessels that go from the inferior tip of the spleen to the splenic flexure of the colon. This may be divided by cautery or may have vessels that need to be controlled with ties or clips during mobilization of the splenic flexure of the colon.

Two ligaments that are variably present are the splenomenal attachments and the splenophrenic attachments (Fig. 73.4). The free part of the greater omentum may have variable association with the splenic capsule along the inferior pole. There are often small vessels that can be controlled by electrocautery. This attachment may be absent or may be quite extensive over the lower pole of the spleen. It is this attachment to the omentum that often leads to disruption of the capsule along this inferior pole causing bleeding during other abdominal procedures

and may necessitate splenectomy for control after an inadvertent injury. Prior to exerting inferior traction on the omentum during any procedure, the extent of attachments to the lower pole of the spleen should be investigated and if present should be carefully divided prior to further mobilization. There may be direct ligaments connecting the spleen to the diaphragm identified as splenophrenic ligaments. These typically are present to a greater degree when the spleen is diseased or enlarged. They may be avascular or may have branches of vessels parasitized from the diaphragm blood supply.

The anatomy of the spleen itself is segmental, with individual segments fed by arteries and drained by veins that leave via the trabecula.¹² The trabecula are fibrous bands that attach to the splenic capsule. The parenchyma of the spleen between these trabecula is divided into a small area of white pulp surrounding the arteries, a marginal zone, and the larger predominant area of red pulp that constitutes 75% of the splenic parenchyma.^{13,14} The capsule of the spleen is quite thin. This consists of a single layer of mesothelium and several layers of fibroelastic tissue. In other mammals but not humans, there may be variable amounts of smooth muscle in the capsule. This smooth muscle allows contraction and mobilization of the circulating blood cells that are stored in the spleen.¹⁵ The trabecular arteries that enter the spleen as continuation of the segmental arterial branches then give off perpendicular branches to form the central arteries (Fig. 73.5). Surrounding these central arteries is the periarterial lymphatic sheath (PALS), which is composed of T lymphocytes as well as follicles with B cells at various stages of development. During antigenic stimulation, this area greatly expands with more mature and secondary follicles. The marginal zone is the border zone between the white pulp and the red pulp; it contains a mixture of lymphatics and macrophages. The structure of the red pulp is made up of splenic cords with an intervening area called splenic sinuses. The splenic cords, also known as the cords of Billroth, are a meshwork of fibroblasts and many mature macrophages. The splenic sinuses are an interconnective meshwork of fairly random red cell spaces that are thin walled and generally filled with many erythrocytes.¹⁴

Studies on blood flow show two alternative routes to the spleen being fast flow and slow flow.¹⁶ A small proportion of the blood goes through the splenic arteries and returns rapidly to the splenic veins. This fast flow pattern consists of a greater predominance of plasma and few erythrocytes because of streaming and accounts for only 10% of flow. A particularly large portion of the erythrocytes that enter the spleen travels through the highly fenestrated meshwork in the red pulp as part of the filtration process of the spleen. This slow path or slow flow composes up to 90% of the splenic blood flow and relates to the role of the spleen in clearing senescent erythrocytes.

Accessory spleens are small nodules of splenic tissue that are completely separate from the main body of the spleen. They commonly range in size from 0.5 cm up to 3 to 4 cm. The incidence of accessory spleens is reported to be between 10% and

FIGURE 73.5. The splenic microanatomy is shown with depictions of both the open and closed circulations.

20%. The most common location for these small nodules of splenic tissue is in the splenic hilum, the omentum (most commonly between the stomach and transverse colon but also within the greater omentum), and the small bowel mesentery. However, they can occur virtually anywhere in the abdomen including the retroperitoneum behind the spleen and in the pelvis. Accessory spleens are important in disease processes in which a complete removal of all splenic tissue is necessary for long-term cure, such as certain autoimmune disorders. The routine use of laparoscopic splenectomy to treat this disorder highlights the importance of the accessory spleens as they are more difficult to identify during a minimally invasive procedure than during an open operation. However, several reports demonstrate that accessory spleens can be successfully removed laparoscopically, particularly with the aid of a nuclear medicine spleen scan if needed to identify sources of residual tissue.¹⁷

PHYSIOLOGY

The major functions of the spleen can be divided into two general categories: hematologic functions and immunologic functions (Table 73.2).¹⁴ For hematologic functions, the spleen is primarily related to the destruction or clearance of the cir-

culating blood cell elements as a normal physiologic mechanism. This physiologic filtration function is increased in disease states that produce hypersplenism. The spleen may play a minor role in hematopoiesis and storage of blood cells that can be mobilized for the circulation; the predominantly stored cell type is platelets. In terms of the immunologic functions, the spleen relates to the vascular system in many of the same ways that lymph nodes relate to the lymphatic system. The white pulp and marginal zones are most important for the immunologic functions whereas the red pulp is primarily related to the hematologic functions. However, the macrophages that line or fill the cords in the red pulp are also important in immunosurveillance for intravascular pathogens.

3 The primary hematologic function of the spleen is removal of senescent erythrocytes or remodeling of abnormal red blood cells, and the recycling of iron by splenic macrophages.¹⁴ The average life span of a normal erythrocyte measured on clearance studies in humans is approximately 120 days.¹⁸ The spleen destroys approximately 100 billion erythrocytes daily in the red pulp. The process of removal or phagocytosis of erythrocytes or other blood cells is called culling (Table 73.2). The blood flow patterns of the spleen lead to a hemoconcentrated erythrocyte-laden fluid that enters the sinuses of the red pulp. Here a slow flow through the sinusoid network with adjacent macrophage-filled cords is the environment in which erythrocytes may become trapped and then phagocytized by the macrophages. The precise mechanism by which senescent red cells are identified for destruction in normal physiology is unclear. One hypothesis is that over the course of the life span of an erythrocyte, there is loss of either membrane elements or total membrane material such that the red cells become less compliant and therefore become mechanically trapped in the mesh of the sinusoids. A second hypothesis is that specific cell surface marker molecules may either become more exposed or less available to allow identification of senescent cells targeted for destruction. Pathologic destruction of red cells occurs in diseases such as hereditary spherocytosis or elliptocytosis in which genetic defect creates abnormal red cell pliability limiting its passage through the red pulp. Similarly, in sickle cell anemia, the genetic defect in the hemoglobin alters red cell shape and creates destruction with clogging of the sinusoids. A second pathologic mechanism in which destruction of red cells is increased occurs in disease processes that increase the spleen size and lead to removal of normal red cells because of increased red pulp volume. This condition is called hypersplenism.

TABLE 73.2

NORMAL FUNCTIONS OF THE SPLEEN

HEMATOLOGIC

- Culling or destruction of senescent erythrocytes
- Pitting or removal of cytoplasm inclusive in erythrocytes
- Reservoir for platelets and granulocytes
- Hematopoiesis—as fetus or in conditions with bone marrow destruction

IMMUNOLOGIC

- Filtration and trapping of circulatory antigens
- Lymphocyte stimulation and proliferation
- Antibody production in germinal follicles
- Production of opsonin-tuftsinn and properdin
- Opsonins: tuftsinn and properdin

The second physiologic process involving circulating erythrocytes is remodeling or pitting, which is partial removal of the cell membrane, typically associated with cytoplasmic inclusions. Erythrocytes with a remnant of the cell nucleus remaining pass more slowly through the splenic red pulp because of their larger size.¹⁴ The nuclear remnant may be trapped passing through a small space in the spleen, and this solid particle that does not allow deformation gets pinched off in the process of pitting. Intracytoplasmic inclusions include Howell-Jolly bodies, which are nuclear remnants; Heinz bodies, which are denatured hemoglobin; and Pappenheimer bodies, which are iron granules.

The destruction of the other circulating cellular elements of the blood (platelets and leukocytes) is typically more pathophysiology of the spleen than normal physiologic function. The disease processes in which these cells are removed are either related to autoantibodies to cell surface elements or to hypersplenism. If either platelets or white blood cells become coated with antibodies, the Fc portion of the immunoglobulin can interact with the Fc receptors on the macrophages in the splenic cords, leading to phagocytosis of these cell types. With splenic enlargement from various causes of hypersplenism, a similar process of destruction can occur even without any autoantibodies or defects in the cells, because of the increase in splenic mass.

The spleen is a potential site for hematopoiesis of all cell types during gestation. In normal humans, there is very little if any production of red cells, granulocytes, or platelets, which is not true in other mammals. In the white pulp of the spleen there are germinal centers with amplification and production of reactive lymphocytes. The cords of the spleen are filled with macrophages, and throughout normal adult life there may be production of lymphocytes and macrophages in the spleen. In certain disease states, the spleen may develop the capacity for erythropoiesis and myelopoiesis. The best example is agnogenic myeloid metaplasia. In this disease, the bone marrow is replaced with fibrotic scar and a portion of the hematopoietic function of the marrow is assumed by the spleen that typically becomes quite enlarged.

The final hematologic function of the spleen is as a reservoir of circulating cellular elements.¹⁵ In humans, the only significant cell type that is stored in the spleen is platelets. It is estimated that 30% of all platelets may reside in the spleen. This function may be more important in other mammals, particularly those with significant smooth muscle lining the capsule of the spleen that allows contracture with expulsion of large numbers of stored cells as a physiologic response to injury.

- 4 The immunologic function of the spleen is to generate an immune response to antigens that are identified and cleared from the blood system (Table 73.2). Either opsonized antigens or specific encapsulated microorganisms are important examples of target antigens trapped by the spleen. The spleen is an ideal environment for generation of either a cellular or a humoral immune response. All of the necessary cell types for stimulation of the immune response are present, including phagocytic cells, dendritic cells, T cells, and B cells, which may form germinal follicles to generate specific antibody responses. These interactions primarily occur in the marginal zone in the white pulp, which may become quite enlarged and hypertrophied during antigen stimulation. These cellular components and the structure of the germinal follicles are essentially identical to those found in lymph node tissue, which becomes enlarged in a similar way with antigenic stimulation via microbes or antigens in the lymphatic system.

The spleen is also involved in nonspecific immune responses. It is the site of synthesis of both properdin and tuftsin, which are opsonins. Tuftsin is a small peptide that binds to the surface of granulocytes and promotes phagocytic function by these cells.¹⁹ Properdin can initiate the alternate pathway of complement activation that can be important in destruction of abnormal cells or bacteria that are antibody bound. The spleen is not the only source of these nonspecific immune-enhancing proteins; therefore splenectomy may lead to only a modest alteration in this function.

PATHOPHYSIOLOGY

There are characteristic responses that share many common features under the broad category of hyposplenism and hypersplenism. These features highlight the normal physiologic functions of the spleen and provide guidelines and influence clinical decision making when managing patients after splenectomy or in deciding which patients should undergo splenectomy. By far, the most common cause of hyposplenism is surgical removal.²⁰ Other causes are an unusual situation of a congenitally small or absent spleen or acquired destruction of splenic tissue as can occur in patients with sickle cell anemia. Hypersplenism is the most frequent indication for elective splenectomy.²¹ There are various causes of hypersplenism that are typically neoplastic but may be related to primary blood cell dysfunction or abnormalities, or other condition such as portal hypertension due to cirrhosis or splenic vein thrombosis.

Hyposplenism

Hyposplenism or the changes that occur after a splenectomy are predictable from the known functions of the spleen. There are hematologic changes in the circulating cells from loss of the splenic functions of culling, pitting, and as a reservoir for platelets (Table 73.3). There are changes in the immunologic responses, important primarily in infants or young children, that can lead to overwhelming postsplenectomy sepsis. The two most common nonsurgical causes of hyposplenism are sickle cell anemia and celiac disease.²¹

The changes in circulating blood cells after splenectomy in cases of hyposplenism affect the erythrocytes, leukocytes, and platelets. Over time, the intracytoplasmic inclusions in the red cells that are normally cleared by the spleen accumulate, resulting in the presence of Howell-Jolly bodies, Heinz bodies, and Pappenheimer bodies. Other changes can include target cells with excess red blood cell membrane and increases in the circulating nucleated red blood cells or reticulocytes. As the spleen is the organ of storage for a large proportion of the platelets, a splenectomy often results in thrombocytosis with platelet counts postsplenectomy frequently surpassing 500,000 and sometimes up to one million. This increased platelet count is often transient and may be a reflection that the spleen as a storage organ for platelets may not be a primary area of platelet destruction after the typical half-life of 10 days. The immediate white blood cell response after a splenectomy is leukocytosis, reflecting storage of a large proportion of white blood cells in the spleen.²¹ As with thrombocytosis, this effect

TABLE 73.3

RESULTS OF SPLENECTOMY/HYPOSPLENIC CONDITION

HEMATOLOGIC

1. Erythrocytes
 - Howell-Jolly bodies (nuclear fragments)
 - Heinz bodies (hemoglobin deposits)
 - Pappenheimer bodies (iron deposits)
 - Target cells
 - Spur cells (acanthocytes)
2. Platelets
 - Transient thrombocytosis
3. Leukocytes
 - Transient leukocytosis
 - Persistent lymphocytosis
 - Persistent monocytosis

is transient but there may be long-term increases in the proportion of circulating lymphocytes and monocytes after splenectomy. Preserving even a small amount of spleen can preserve splenic clearance of senescent blood cells.²²

The changes in immune function that occur with hyposplenism or after splenectomy are most importantly manifest by the phenomenon of overwhelming postsplenectomy sepsis.^{23,24} This was initially recognized as an important epidemiologic phenomenon in the early 1950s, and multiple studies of splenectomized patients define key features of this increased susceptibility to infection. It is clear that the risk of postsplenectomy sepsis is inversely related to age.²⁵ The younger the child is, the greater is the impact and risk of developing overwhelming postsplenectomy sepsis.²⁶ This feature has clinical implications; for example, elective splenectomy should not be generally performed for patients with hereditary erythrocyte syndromes until after 6 to 10 years of age. For adults, there is a 40% to 60% increased risk of sepsis compared to people with normal splenic function. These postsplenectomy septic episodes typically occur within the first 2 years after splenectomy in 80% of the cases. In adults, the reason for the splenectomy also relates to the incidence of sepsis. After splenectomy for trauma, the instance of sepsis in a large series was 1.4% whereas splenectomy for thalassemia was associated with an incidence of 24.8%. Patients with any associated immunodeficiency such as malignancy or patients undergoing chemotherapy for treatment of Hodgkin disease are also at increased risk for sepsis. The mortality rate of postsplenectomy sepsis is 50% to 60% in most series.

5 Typically, encapsulated organisms cause the postsplenectomy sepsis-related infection. These bacteria have special features that allow them to be opsonized and cleared from circulation by the spleen, making them more dangerous in hyposplenic or splenectomized patients. The most common organism causing postsplenectomy sepsis is *Streptococcus pneumoniae*, which accounts for 50% of septic episodes in most series. In decreasing order of frequency, other bacteria associated with postsplenectomy sepsis are *Haemophilus influenza*, *Neisseria meningitidis*, β -hemolytic streptococcus, *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas* species.²⁵ The current recommendations for patients who are having elective splenectomy are to vaccinate susceptible individuals to pneumococcus strains (Table 73.4).²⁵ This is ideally done 2 weeks before the operation if possible, but should be done at any time preoperatively or even postoperatively if the patient was not vaccinated. Recent studies have shown that administration of vaccine with the first postoperative visit does not lead to beneficial immune stimulation. Waiting for 14 days postoperatively is equivalent to waiting 1 month or longer.²⁷ Therefore, vaccination at 2 weeks after an unplanned splenectomy is ideal timing. Polyvalent vaccines, including Pneumovax 23, and Pnu-Immune 23, provide protection against virtually all common strains of pneumococcus.²⁷ For patients who are at particularly high risk because they may be immunosuppressed, there are also polyvalent vaccines against *Neisseria meningitidis* and *Haemophilus influenza* type B. Patients younger than the age of 2 years and patients receiving chemotherapy for

malignant disease may not be able to generate an immune response to vaccines and should be vaccinated either after age 2 years or when not receiving chemotherapy. Finally, because of the risk of very rapid progression of sepsis in a postsplenectomy state, patients who have had splenectomy for any reason should be given a medic alert bracelet.

Two recent studies highlight the incidence of increased relative risk and number of infections after splenectomy. The relative risk for infection within 90 days of a splenectomy was 10.2% compared to 0.6% in the general population. In patients undergoing appendectomy for acute appendicitis, a control group undergoing an abdominal procedure, there was still increased risk of infection in splenectomy of 10.2% compared to patients who had appendectomy of 4.2%.²⁸ The relative risk of postsplenectomy infection decreased over time with an overall hazard ratio of 4.6-fold between 90 days and 365 days after splenectomy and 2.5-fold for more than 365 days after splenectomy.²⁸ There is definite evidence that increased use of vaccination decreases this risk of infection. Another large national study from Scotland showed that the overall rate of first severe infection was 7.0 per 100 person-years after splenectomy. In that subgroup of patients who had a severe infection, the rate of subsequent infections was significantly increased, and the second severe infection rate was 44.9 per 100 person-years, and a third episode of severe infection was 109.3 per 100 person-years.²⁹ This indicates that the patients who had significant postsplenectomy sepsis should be observed very closely and counseled on seeking medical attention for any sign of any infectious process. The increased trend, particularly after blunt splenic trauma and other hematologic diseases, toward splenic preservation by splenorrhaphy or partial splenectomy, is accompanied by an increased risk of infection in these patients comparable to patients who have a complete splenectomy.³⁰

A recent survey of practicing surgeons reviewed patterns of use of immunization for splenectomy patients. Virtually all (99.2%) of active surgeons indicated that they do immunize patients they treat with splenectomy.³¹ Nearly everyone administered vaccine to pneumococcus; 72.4% of practicing surgeons routinely used a *Haemophilus influenza* type vaccine, 62.8% gave meningococcal vaccination, and 56.7% used all three vaccines. A few practicing surgeons immunized their patients who had splenorrhaphy (15.7%), and a very small proportion immunized patients who had splenic injury but were managed nonoperatively. Current guidelines are that all patients with elective splenectomies should have prophylactic immunization prior to surgery whereas patients who have unexpected splenectomy should have immunization 14 days after the procedure. All patients should get pneumococcal vaccines, and patients at high risk should have vaccination for *H. influenza* and meningococcus.^{31,32}

For decades it has been known that patients after splenectomy are susceptible to infections as just described. It has only recently been realized that there are various vascular complications that occur to a greater degree in patients with splenectomy than in a cohort of abdominal surgery patients without splenectomy.³³ These include arterial thrombosis, venous thrombosis, and pulmonary artery hypertension. Data from patients with hereditary spherocytosis who have undergone splenectomy report between a 5.6- and 7.2-fold increase in ischemic heart disease compared to patients who do not have splenectomy. The most marked finding for arterial events occurs in thalassemia in which patients who undergo splenectomy have a 20-fold increase in arterial atherosclerosis of arterial structures. Acute portal venous thrombosis is reported after splenectomy in one series up to 4.8% for various patients.³⁴ It is clearly more common after splenectomy in patients with cirrhosis and hypersplenism, when the rate of portal vein thrombosis may be 30% to 40%.³⁵ However, the incidence of venous thrombosis may extend beyond the mesenteric/portal venous system and include deep venous thrombosis in the pelvis and lower extremities as well as subsequent pulmonary embolus to a much greater extent. This

TABLE 73.4

GUIDELINES FOR PREVENTION OF POSTSPLENIC SEPSIS

- Vaccinate with polyvalent pneumococcal vaccine at least 10–14 days prior to splenectomy, if possible.
- If splenectomy is urgent, wait until at least 14 days postprocedure to vaccinate
- For high-risk patients (immunosuppressed, children <10 years of age), meningococcal vaccine and *Haemophilus influenza* vaccine
- Antibiotic prophylaxis for children <5 years of age
- Early antibiotic treatment for initial signs of infection
- Medi-Alert bracelet

also has led to increased evidence of pulmonary arterial hypertension in patients after splenectomy for hematologic diseases.

The pathogenesis of these vascular events after splenectomy is likely multifactorial.³³ They may involve some element of hypercoagulable state due to altered platelet function and number. There may be some disturbances in vascular epithelium related to other blood elements that are altered after splenectomy. There is also evidence that there are changes in lipid profiles after splenectomy that could promote atherosclerosis and thrombosis.³³ Although these vascular events clearly are increased in frequency, they do not occur in an overwhelming number of patients. This phenomenon does mitigate toward using splenectomy conservatively, particularly in high-risk individuals such as patients with thalassemia.

Hypersplenism

Hypersplenism is increased splenic function that is manifested clinically by the decrease in one or more of the circulating blood elements (Table 73.5). The specific criteria for hypersplenism are as follows: (a) documented anemia, thrombocytopenia, or leukopenia; (b) normal compensatory response by the bone marrow to correct the cytopenia; and (c) correction of this cytopenia by splenectomy. Some definitions of hypersplenism may also include splenomegaly among the criteria. If an enlarged spleen is mandatory for hypersplenism, then diseases or disorders of circulating blood cells such as idiopathic thrombocytopenic purpura (ITP) or autoimmune hemolytic anemia would not be included. A second approach to defining hypersplenism is to categorize disorders in which the spleen is normal anatomically and the disease is related to the circulating cells, distinguished from a second category in which the circulating cells are normal and there is a primary anatomic or functional alteration of the spleen (Table 73.6). For either situation the pathophysiology is that the spleen is the site of destruction for one or more circulating blood elements. In cases of a significantly enlarged spleen, additional symptoms can be caused by mass effect from the spleen on adjacent organs. The most important symptom is early satiety and weight loss as the stomach is compressed between the liver and the enlarged spleen. Hypersplenism is the most important indication for elective isolated splenectomy to reverse the cytopenia and often to relieve compressive symptoms from splenomegaly.

TREATMENT OF DISORDERS OF THE SPLEEN

Splenic Surgery

Until recently, the only pertinent operation involving the spleen was splenectomy. Appreciation of the increased risk of infection in patients who are asplenic or hyposplenic in the late

TABLE 73.6**CAUSES OF HYPERSPLENISM**

1960s and the early 1970s led to two new surgical procedures. First, there was an interest in splenic preservation with procedures including splenorrhaphy and other ways to save damaged spleen. Second, procedures for partial splenectomy were developed primarily for elective surgery in which hypersplenism existed but a complete splenectomy was not necessary. The most recent change in surgery of the spleen relates to the advancements in minimally invasive surgery over the past 15 years.³⁶ Laparoscopic excision is ideal for many splenic operations, and recent reports have used laparoscopic splenectomy for virtually all indications including removal of massive spleens. In most major centers, laparoscopic splenectomy is now the procedure of choice for elective splenectomy.

To better describe and understand operative indications in surgery of the spleen, one could categorize the splenectomy or procedures of the spleen into eight general areas:

1. Trauma or injury to the spleen.
2. Autoimmune/erythrocyte disorders. In this category of disease, there are specific cytopenias related either to antibodies targeting platelets, erythrocytes, or neutrophils, or anemia due to intrinsic structural changes within the erythrocyte. During these procedures, it is typically important to obtain total splenectomy for complete cure.
3. Hypersplenism results in decreased circulating blood cells often including all subtypes of platelets and red blood cells. Hypersplenism may be related to neoplastic infiltration of the spleen or infiltration with lipids and other stored products that leads to a massive spleen. Hypersplenism also may cause symptoms due to the splenic size.

4. Incidental splenectomy. The spleen may be removed as part of a standard operation to remove the distal pancreas most commonly, and also for proximal gastric cancers due to the direct or nodal involvement. Other enlarged tumors of the left upper quadrant and retroperitoneum including sarcoma and adrenal tumor, and left nephrectomy, may require splenectomy because of association with the spleen or its vessels although it is not a primary tumor of the spleen.
5. Iatrogenic splenectomy. This is a category that may be underreported but relates to the splenectomy or splenic preservation procedures due to incidental injury to the spleen during procedures within the general abdominal cavity or specifically, the left upper quadrant.
6. Diagnostic procedures. In some cases, the spleen is removed primarily to make a clinical diagnosis.³⁷ An example of this is staging laparotomy for Hodgkin disease, though this is now mainly a historical footnote as the treatment of this lymphoma now rarely requires splenectomy to make the diagnosis.
7. Vascular procedures. Splenectomy during vascular procedures includes treatment of patients with splenic vein thrombosis or less commonly splenic artery aneurysms.
8. Miscellaneous procedures. Treatment of simple and neoplastic cysts, echinococcal cysts, and treatment of the wandering spleen when symptomatic as a congenital anomaly.

There were an estimated 22,000 splenectomies performed in the United States in 2005.²¹ Two recent reports have been published describing 10-year experiences for all splenectomies done in their respective institutions. The first report is the combined series of 1,280 splenectomies over a 10-year interval from the Barnes Hospital in St. Louis and the Brigham and Women's Hospital in Boston.³⁷ The second report is a single institution over the identical time period from Vanderbilt University.³⁸ In the Barnes/Brigham series, there were 1,280 splenectomies and in the Vanderbilt series there were 896 splenectomies (Table 73.7). Dependent on the type of institution and referral patterns, the indications for splenectomy vary to some degree. In the Vanderbilt series most splenectomies were done for trauma, accounting for 41.5% of all operations done in that institution. In the Barnes/Brigham and Women's

series, the most common indication was incidental splenectomy in which the spleen was removed as part of an excision of another organ, typically a large tumor in the left upper quadrant of the abdomen. The second most frequent indication for splenectomy was staging laparotomy for Hodgkin disease. This is likely to be different in the ensuing decade as both treatment indications as well as diagnostic techniques have significantly eliminated this practice since 1990. These differences highlight that, in the centers that have a large trauma population, splenectomies are done for that indication whereas in centers with major cancer referral bases, there are alternative indications. If one eliminates the traumatic, incidental, and staging procedures, the most common indication in both series is autoimmune or erythrocyte disorders.

Splenic Trauma

- 6 The spleen is the most common intra-abdominal organ injured by blunt trauma in the United States, and in many institutions splenectomy remains the most common operative procedure performed on the spleen.³⁹ The history of splenic surgery mirrors the history of surgery for trauma. In the ancient medical literature, the spleen often herniated through a flank wound and there are reports of either partial splenectomy or total splenectomy of the herniated portions.⁴⁰ The first documented splenectomy for penetrating trauma was performed in San Francisco by a British naval surgeon named O'Brien in 1816 when a spleen protruded out the side of a knife wound.¹² In the late 19th century, Theodor Billroth observed during an autopsy of a patient who died of head trauma 5 days earlier that there was minimal blood in the peritoneum from the fracture of the splenic capsule and predicted that these injuries may be managed operatively. Although in the earlier part of the 20th century splenic trauma was uniformly managed by a complete splenectomy, Dr. Campos Christo of Brazil reported partial splenectomy and splenic salvage for both penetrating and blunt trauma in 1962 (Table 73.1).^{2,4} This initial report, combined with the ability to obtain repeated cross-sectional imaging, with the understanding of splenic function and with

the appreciation for overwhelming postsplenectomy sepsis, has led to the current guidelines for nonoperative management of lower-grade splenic injuries and operative management centered around splenic preservation when possible.⁴¹

The most common modes of blunt injuries leading to splenic rupture are motor vehicle accidents and bicycle accidents, in which upper abdominal trauma may occur. The signs and symptoms of isolated splenic injury are tenderness in the left upper quadrant of the abdomen. Attention toward the lower lateral left ribs and focal tenderness over ribs 9 through 11 in that region should raise suspicion of possible splenic injury. Approximately 20% of cases of rib fracture can be demonstrated on radiographs. Patients may have referred pain to the left shoulder (the Kehr sign), particularly when placed in the Trendelenburg position with palpation of the upper abdomen. The spleen itself is rarely palpable, but when a left upper quad-

rant mass is palpable it can represent contained or subcapsular hematoma; this is known as the Ballance sign. Depending on the severity of the injury, patients may have no hemodynamic instability or may be in frank hypovolemic shock. The staging system for splenic trauma is shown in Table 73.8.

The laboratory abnormalities associated with splenic rupture include a decrease in hematocrit and hemoglobin, although initial assessment before volume resuscitation may show normal levels. After a short period of time there is often a leukocytosis of 15,000 to 20,000. Plain abdominal X-ray views may show left rib fractures and displacement or a corrugated appearance along the greater curvature of the stomach due to a hematoma infiltrating the gastrosplenic ligament (Fig. 73.6). Peritoneal lavage can reveal the presence of blood in the abdomen. The most important current tool for diagnosis is the CT scan, particularly in patients who have enough hemodynamic stability to be managed conservatively. Contrast CT scan shows the splenic contour and also demonstrates the amount of extrasplenic blood (Fig. 73.7).⁴²

Blunt injuries constitute most splenic trauma, but the spleen is susceptible to penetrating trauma either in the retroperitoneum, lower thoracic region, or upper abdominal area. A 15-year state review of splenic trauma in Pennsylvania reported 10,652 (92%) blunt injuries and 893 (8%) penetrating injuries.⁴¹ The management and diagnosis of penetrating trauma of the thorax and upper abdomen is less of a diagnostic

FIGURE 73.6. Abdominal film in a patient with a splenic rupture from blunt trauma with a perisplenic hematoma displacing the greater curvature of the stomach medially. The scalloped appearance is indicative of blood in the gastrosplenic ligament. (Radiograph courtesy of Dr. C. William Schwab.)

dilemma as most of these patients undergo abdominal exploration because of associated injuries. In some series, there are additional injuries in 90% to 100% of patients with penetrating trauma to the spleen and 40% to 60% of patients with associated injuries for blunt trauma.

Management of splenic injuries historically has been a laparotomy with splenectomy. Since Christo introduced the ability to do either partial splenectomy or splenorrhaphy, there has been an increased trend with surgical procedures to try to repair or preserve part if not all of the spleen. The current trend in management is a nonoperative approach with observation by serial CT scans.⁴³ The presence of peritonitis, associated injuries requiring surgery, the overall injury severity, evidence of hypovolemic shock and ongoing bleeding, and the patient's age are the primary factors that affect decisions regarding nonoperative versus operative management of blunt splenic injuries.⁴¹ When patients have diffuse peritonitis or if patients have hypotension related to hypovolemic shock, urgent laparotomy is indicated (Fig. 73.8). For patients who are hemodynamically stable and do not have other injuries that require surgical management, the recommendation is to attempt nonoperative observation.

The standard nonoperative management protocol includes very close observation in an intensive care unit or a similar monitored environment. Patients have serial abdominal exams as well as serial hemoglobin and hematocrit assessments. Any change in the status of a stable patient is evaluated by CT scan to assess for progressive or ongoing bleeding demonstrated by increased hemoperitoneum or expansion of splenic hematoma. A recent report noted that routine follow-up CT scans did not alter management in patients treated nonoperatively.⁴⁴ Only patients with changes in hemodynamic parameters had a change in management. With this conservative management, most patients avoid laparotomy for isolated splenic blunt trauma.⁴⁵ If patients are older, have associated injuries, or have ongoing blood loss, a laparotomy is appropriate for blunt splenic trauma.^{40,46} The nature of the splenic injury is graded relative to the degree of damage to the splenic parenchyma and the proximity to the splenic hilum and major blood vessels (Table 73.8). The principles of operative management include stopping ongoing hemorrhage while preserving the maximal amount of viable splenic parenchyma. Nonviable or devascularized tissue must be debrided.⁴⁷ Partial splenectomy has been used based on the concept of segmental blood supply via the trabecular arteries. Various approaches can be taken to more minor peripheral splenic trauma including primary repair or mesh repair (Fig. 73.9). Multiple materials that are available for hemostasis including microfibrillar collagen, thrombin-soaked Gelfoam, or fibrin glue sealants have been used to obtain control of splenic hemorrhage. The argon beam coagulator is a very useful instrument for capsular tear or avulsions. Of note, all of these techniques that have been applied to the patient suffering from blunt trauma can be similarly applied to patients who have inadvertent trauma to the spleen during operations on the splenic flexure of the colon or the left kidney, adrenal gland, or stomach.

Over the past decade, this increasing trend toward nonsurgical management has expanded the number of patients who were not explored and increased the overall success rate of conservative management. A recent study of more than 625 patients with blunt trauma showed that there was an increase in initial nonoperative management from 61% to 85%.⁴⁸ The success rate of nonoperative management increased from 77% to 96% and the splenic salvage rate from 57% to 88%.⁴⁸ Part of this may be due to a decreased distribution of more severe splenic injuries and part of it may be due to a trend toward use of embolization of splenic arteries as part of the nonoperative management of blunt trauma.

Since its introduction in 1992 as a potential maneuver to improve the nonoperative management of blunt splenic injury, embolization, with either coils or Gelfoam, of either proximal or distal splenic vessels, has become more common.⁴⁹ In a

FIGURE 73.8. A and B: Rapid mobilization of a bleeding spleen can be accomplished in most patients by blunt dissection of the lateral attachments. C: The splenic hilum can then be quickly controlled.

study comparing the outcome of blunt trauma over the past two decades, the use of embolization increased from 2.7% to 22.6%.⁴⁸ Most studies provide similar data showing that the overall success rate for nonoperative management is improved with the use of splenic artery embolization, including a

FIGURE 73.9. A: Techniques to suture superficial splenic lacerations. B: Technique to control bleeding after hemisplenectomy. The sutures can be interlocked. C: Polyglycolic acid mesh sheets or mesh bags can be applied to spleens that have had the capsule stripped away.

decreased use of blood products.⁵⁰ Some recent studies have stated that embolization may be overused; one reported a failure rate of 27% in patients with embolization who then needed surgical exploration.⁵¹ Again, these comparative studies are not matched in terms of severity of injury or even the techniques used for the splenic artery embolization.

One issue with the nonoperative management of blunt splenic trauma is the risk of delayed rupture. Standard guidelines of conservative management are that patients should have stable hemoglobin for 36 to 48 hours and have resolution of abdominal pain prior to discharge. The delayed rupture rate in a large series of more than 1,900 patients showed that 27 patients were readmitted for splenectomy after discharge.⁵² This is a delayed rupture rate of 1.4%.⁵³ The median time from injury to readmission for splenectomy was 8 days with a range of 3 to 146 days. Similar results were obtained in an institutional study of 450 patients with nonoperative management of blunt splenic injury. In this group, 4% failed with eventual splenectomy due to delayed rupture.⁵² Both studies stress that with increased use of nonoperative management, the potential risks of delayed rupture require very specific instructions to patients, emphasizing that re-onset of acute abdominal pain with other signs and symptoms of hypotension requires emergent transportation to the nearest emergency room or hospital facility.

Atraumatic splenic rupture is an unusual occurrence. This spontaneous rupture occurs primarily with enlargement of the spleen due to malignant disorders with either primary or secondary metastases, infectious or inflammatory diseases, or

mechanical causes such as pregnancy or peripartum rupture. In a large series of more than 900 patients with atraumatic spontaneous rupture of the spleen, only 6.4% had no pathologic or mechanical causes that were identified.⁵⁴

Autoimmune Disorders

Some splenic disease originates in either autoimmune phenomena or intrinsic diseases within circulating cells that lead to their destruction rather than histology, pathology, or size of the spleen. The most common example of this is immune thrombocytopenic purpura (ITP) in which antibodies to platelet antigens lead to destruction of platelets and thrombocytopenia, with the spleen being the primary source of platelet elimination. Related diseases affecting erythrocytes and neutrophils with specific antibodies and splenic elimination occur less frequently.

Immune Thrombocytopenic Purpura. Immune thrombocytopenic purpura (ITP) is a diagnosis of exclusion once various other causes such as drug-induced thrombocytopenia or evidence of bone marrow failure are eliminated.⁵⁵ ITP is a disease characterized by autoimmune destruction of platelets with clinical manifestations of thrombocytopenia such as easy or excess bleeding.⁵⁶ ITP occurs as an acute form and a chronic form. Acute ITP generally appears in children younger than 8 years of age following a viral upper respiratory illness. Eighty percent to ninety percent of children with acute ITP have

spontaneous remissions.⁵⁷ Only 8% to 10% of adults who develop ITP have remission, and most develop chronic ITP. ITP is usually self-limited and requires surgical intervention only in the case of intracranial bleeding. Chronic ITP accounts for the vast majority of cases considered for splenectomy. Similar to autoimmune hemolytic anemia, this disease can be idiopathic or secondary to a lymphoproliferative disorder, connective tissue disorder such as systemic lupus erythematosus, or drug or bacterial exposure. Diagnosis averages in the fourth decade of life, and it affects women more commonly than men. As HIV was identified in the mid-1980s, patients with acquired immunodeficiency syndrome (AIDS) developed disease virtually identical to ITP.⁵⁸ Patients with newly diagnosed ITP and risk factors for HIV should undergo testing for HIV infection.

7 The pathophysiology of ITP is development of an IgG antibody to a platelet antigen. This is most commonly directed against the fibrinogen receptor (glycoprotein IIb/IIIa and IR/IX).⁵⁹ The spleen plays a predominant role in this disease as it may be the site of initial antibody production⁶⁰; it is almost certainly the site of continued antibody production, and in most patients the spleen is the primary site of platelet destruction. Since the targeted antigen is an intravascular cell, and since the spleen stores large numbers of platelets, the initial reaction to the platelet cell antigen may occur in the spleen. Antibody levels indicate that overall IgG production in spleens from patients with ITP is markedly increased over individuals with normal spleens. Similarly, following splenectomy the amount of IgG antibody is somewhat decreased. The spleen is also the predominant site of platelet destruction. The macrophages located in the cords of Billroth have receptors for the Fc portion of the IgG and bind and phagocytize the antibody-coated platelets. A second, more recently described component of the pathophysiology is an inappropriately decreased level of production of thrombopoietin for the level of thrombocytopenia. Cloning of the thrombopoietin receptor or the megakaryocytes has led to several new agents that can alter this aspect of the pathophysiology of ITP.^{61,62}

To be diagnosed to have ITP, the platelet count must be less than 100,000, but patients do not typically become symptomatic unless platelet counts are less than 50,000. Platelet counts in this disorder may drop to very low levels, less than 10,000 on occasion. Assays are now available to identify the IgG antiglobulin on the platelet surface verifying the disease, but more than one third of the patients have no identified antiplatelet antibodies. Bone marrow analysis shows increased megakaryocyte production as compensatory mechanism to the thrombocytopenia. In this disorder, there is usually no splenomegaly and the spleen may be somewhat smaller than typical. Only 2% of patients with ITP have palpable spleens. There is virtually no leukopenia or anemia associated with ITP hypersplenism. Anemia can occur secondary to chronic blood loss. The risk of a fatal hemorrhage in patients with ITP overall is 0.47%/year, and for patients with platelet counts less than 30,000 mortality ranges between 1.6% and 6.9%.⁵⁷

The treatment of ITP includes standard measures to treat any ongoing bleeding, medical therapies designed to increase platelet count, and splenectomy. First-line medical therapy options include platelet transfusion, corticosteroid therapy, gamma-immunoglobulin, and the recently approved Rho(d) immunoglobulin.⁶³ Platelet transfusions should be limited unless patients are actively bleeding as platelets become rapidly coated with IgG and then sequestered and destroyed in the spleen. High-dose corticosteroid therapy produces an initial response in most patients, but this is usually not sustained. Approximately 75% of patients have an increase in platelet count that is significant within 24 hours of starting high-dose steroids.⁶⁴ However, only 15% to 25% of patients with chronic ITP have a sustained remission following steroid therapy. Intravenous IgG immunoglobulin takes between 3 and 5 days to show an effect and generally does not put patients into complete remission. The mechanism of action of immune gamma globulin is believed to be saturation of the Fc receptors

on the splenic macrophages.⁶⁵ The administered gamma globulin may coat red cells, and they may provide a competitive interference such that platelet destruction is decreased. The newest available drug is the recently approved Rho(d) immunoglobulin, which specifically targets the Fc receptors.

In patients who have not achieved a sustained remission with medical therapy, which is most patients with chronic ITP, an elective splenectomy is recommended. A large series analyzed 135 institutional reports between 1966 and 2004⁶⁶ and reported results in terms of normalization of platelet counts, predictive features that would indicate who would benefit from splenectomy, and reported complications including morbidity and mortality (Table 73.9). The fraction of patients who achieved a normal platelet count after splenectomy was 68.9% with more than 5,000 patients reported. Of case series with adults only, this was slightly lower at 66%, and when adults and children were combined it was 72.1%. These results seem to be durable as the 20% of patients with 5-year follow-up demonstrated a similar cure rate of 67.2% (Table 73.9).⁶⁶ A recent study indicated that only patients with short disease duration at a young age (<16 years) had a higher likelihood of cure on univariate analysis, whereas only the short duration of disease was a feature in multivariate analysis.⁶⁷ In the review of the 135 combined series, there was no predictive value of any of these features in terms of which patients would respond to therapy. Overall initial complete response rate to open or laparoscopic splenectomy is about 60%, and 15% to 20% of the initial responders develop relapse with long-term follow-up. One cause for a failed splenectomy for ITP is residual splenic tissue, most commonly a missed accessory spleen or splenosis.¹⁷ Both accessory spleens and splenosis are believed somewhat more common in the current era of laparoscopic splenectomy. Again, ITP spleens are predominantly small and are ideally suited for a laparoscopic approach. The incidence of accessory spleens identified with open procedures is in the range of 10% to 15% whereas the incidence of accessory spleens reported with the laparoscopic approach is between 5% and 12%.⁶⁸ The overall mortality from splenectomy in this patient population is 0.81% and may be slightly lower after laparoscopic splenectomy than after open. This may reflect decreased risk with laparoscopic splenectomy.⁶⁹ This mortality rate, particularly with laparoscopic splenectomy, compares favorably to the risk of a fatal hemorrhage in patients who have significant thrombocytopenia with this disease. The overall complication rate was 12%.

Third-line treatment for ITP after splenectomy failure has been accomplished with various new agents. There were initially several studies with rituximab, which is a chimeric humanized monoclonal antibody directing CD20 against B cells.⁷⁰⁻⁷² It was primarily developed to treat lymphoma, but it has been used in autoimmune disorders and has been tried in phase 2 studies for chronic splenectomy failure ITP. Response rates have been between 25% and 50%. A more promising third-line therapy is agonist agents to stimulate the thrombopoietin receptor on megakaryocytes. There is decreased thrombopoietin production for the degree of thrombocytopenia in ITP. Romiplostim, a fusion protein agonist for thrombopoietin receptor administered by subcutaneous injection, led to response rates of 49% versus 2% for placebo with an overall clinical response of 83%.^{59,73} An oral nonpeptide thrombopoietin receptor agonist, eltrombopag, has recently been studied and shows response rates of 59% versus 16% in a placebo-controlled trial.^{74,75} Although now proven as effective third-line agents after splenectomy failures, they may be useful as initial therapies for patients who cannot tolerate steroids or patients who are splenectomy candidates who are very high risk for surgery. Future studies will define the role of this new class of compounds and may decrease the incidence and need for splenectomy.

Thrombotic Thrombocytopenia Purpura. Thrombotic thrombocytopenia purpura (TTP), or Moschowitz syndrome,

TABLE 73.9**RESULTS FROM 135 COMBINED CASE SERIES EVALUATING SPLENECTOMY FOR ITP**

CURE RATE		
% of patients with normalized platelet counts		
All reports	68.9%	(3,506/5,086)
Adult series only	66.0%	(1,731/2,623)
Adult pediatric combined	72.1%	(1,785/2,468)
% of patients with normalized platelet counts With 5-year follow-up	67.2%	(779/1,159)
COMPLICATIONS		
Perioperative mortality		
Total	0.81%	51/6,256
Laparotomy	0.96%	48/4,955
Laparoscopy	0.23%	3/1,301
Perioperative complications		
Total	12.0%	406/3,386
Laparotomy	12.9%	318/2,465
Laparoscopy	9.6%	88/921

is a poorly understood much more virulent syndrome than ITP in which thrombocytopenic purpura is only one manifestation. This disease is characterized by widespread occlusion of arterioles and capillaries by hyalin membranes composed of platelets and fibrinogen. The classic pentad of symptoms reflects injury to various organs by this microvascular process. This includes thrombocytopenic purpura, with microvascular disease in the skin, neurologic manifestations due to microvascular disease in the central nervous system, renal failure or hematuria due to microvascular disease in the kidney, microvascular hemolytic anemia due to destruction of red cells traveling to damaged small vessels, and fever. The precise etiology is unknown but may be related to an autoimmune response to a small vessel endothelial cell antigen.

The therapeutic options for this disease include administration of fresh frozen plasma and/or plasmapheresis, high-dose corticosteroids, and antiplatelet drugs.⁷⁶ The benefits of plasmapheresis indicate that there is a circulating toxic substance contributing to the etiology, whereas the benefit of administration of fresh frozen plasma indicates lack of some necessary substance yet to be identified. High-dose corticosteroids also have some benefit. Aspirin and dipyridamole block platelet agglutination. A combination of these therapies now leads to significant improvement of symptoms in 70% of patients. For patients failing to respond or patients who relapse, splenectomy has been performed with some success.^{77,78} Most of the long-term survivors with TTP have undergone splenectomy, implying that this organ has some major role in the pathophysiology of this disease.⁷⁹ The precise mechanism of splenic contribution is unclear. Mortality rates in the past have been as high as 90% to 95% for this disorder but are improving with aggressive treatment plans and a better understanding and diagnosis of this disorder.

Autoimmune Hemolytic Anemia. Autoimmune hemolytic anemia or acquired hemolytic anemia results from antibodies produced to red cell membrane proteins that lead to red cell destruction. This disease is more common in women than men with a ratio of 2:1, and it typically presents in patients older than 50 years of age. Patients present with acute symptoms of anemia, jaundice, and occasional fever. The spleen is enlarged in

approximately one half of the patients. Laboratory diagnosis shows a positive direct Coomb test indicating antibodies coating erythrocytes. There is also significant reticulocytosis and increased indirect bilirubin in the serum.

The disease is either idiopathic, in 40% to 50% of the cases in which no identified drug or infectious cause is identified, or secondary to infection or drug. Of the secondary cases, the most common infections are mycoplasmal pneumonia, viral infections, infectious mononucleosis, and AIDS. Neoplastic diseases such as leukemia and lymphoma can also precipitate the syndrome. The major drugs that cause secondary autoimmune hemolytic anemia are penicillin, quinidine, hydralazine, and methyldopa.

Autoimmune hemolytic anemia is also categorized by presence of either cold antibodies or warm antibodies. Warm antibodies are predominantly IgG whereas cold antibodies are predominantly IgM. This distinction is important when considering splenectomy as a treatment. The spleen contains macrophages that bind the Fc portion of IgG. In patients with warm antibody hemolytic anemia, the spleen is the primary source of destruction of the red cells by the red pulp macrophages. However, since the spleen does not contain receptors to bind IgM (the cold antibodies), there is no destruction of the red cells in this form of hemolytic anemia. Rather, IgM either causes complement fixation with destruction of red cells predominantly in the liver, or there is agglutination of red cells in peripheral circulation (such as the distal extremities) leading to peripheral red cell destruction with clinical manifestations similar to the Raynaud phenomenon. Splenectomy for patients with cold antibody or IgM hemolytic anemia is not effective.

The initial treatment of autoimmune hemolytic anemia consists of supportive therapy such as blood transfusions. For patients who have disease secondary to an acute infection such as mycoplasma pneumonia, the disease may be self-limited. For drug-induced hemolytic anemia, the offending agent is removed as quickly as possible. The initial form of treatment is typically high-dose corticosteroids, which cause a beneficial response in 75% of the patients. If patients have drug-induced disease and the offending agent is removed or the acute infection resolves, this may lead to long-term resolution. In idiopathic

autoimmune hemolytic anemia, only 25% of patients have sustained remission from corticosteroid therapy. In patients who have relapse after steroid therapy or who are ineligible for steroid therapy and have warm antibodies, a splenectomy has a high likelihood of benefit. Eighty percent of patients have a good response in correcting the anemia by splenectomy.⁸⁰ This is almost certainly related to removal of the site of destruction of the erythrocytes but also may be due to decreased production of antibodies.

Autoimmune Neutropenia (Feltz Syndrome). Approximately 1% of patients with chronic rheumatoid arthritis develop splenomegaly and neutropenia. This triad of rheumatoid arthritis, neutropenia, and splenomegaly is known as Feltz syndrome.⁸¹ High levels of IgG have been identified on the surface of neutrophils with evidence of increased production of granulocytes in the bone marrow. Pathologic analysis of spleens removed in patients with Feltz syndrome show a significant but proportional increase in the white pulp of the spleen compared with other conditions of splenomegaly.⁸² Microscopically, there is evidence of excess accumulation of neutrophils in the T-cell zone and the white pulp, as well as within the cords and sinuses of the red pulp.

Patients with this disease have recurrent infections due to neutropenia as well as dysfunction of the available neutrophils that are coated with antineutrophil IgG. Recurrent infections as well as chronic leg ulcers are the predominant symptoms. Symptomatic patients should undergo splenectomy, and the vast majority of patients have resolution of their neutropenia within 2 to 3 days.⁸³ Even patients who do not have a significant increase in neutrophil count should get some benefit because of improved neutrophil function.⁸⁴

Erythrocyte or Platelet Structure Disorders

These diseases are not autoimmune phenomena, but rather, intrinsic cellular defects that lead to a shortened half-life of specific blood components primarily precipitating elimination within the spleen. A normal role of the spleen is to eliminate senescent erythrocytes. If erythrocytes have altered structure, this may lead to more rapid elimination. In other diseases, genetic differences in the hemoglobin may result in changes in splenic clearance of cells, particularly in the hypoxic environment that exists within the splenic sinusoids. The most prevalent example of this is sickle cell anemia. A parallel condition occurs in the platelets in Wiskott-Aldrich syndrome, which is an alteration in a cellular adhesion molecule that leads to increased platelet destruction in the spleen and thus to thrombocytopenia.

Hereditary Spherocytosis. Hereditary spherocytosis, also known as congenital hemolytic jaundice or familial hemolytic anemia, is an autosomal dominant disease and the most common of the congenital hemolytic anemias. It affects 1 in 5,000 individuals.⁸⁵ There are various genetic defects in this syndrome that primarily affect spectrin and ankyrin, which alter the binding of the cytoskeleton to the erythrocyte cellular membrane causing decreased cellular plasticity with membrane loss.⁸⁶ The normal shape of the erythrocyte is changed from the biconcave disc into a sphere, and the decreased membrane to cell volume ratio causes a lack of deformability, which affects the passage of erythrocytes through channels of the splenic red pulp. Due to this delay in cell transit, there is ATP deprivation resulting in increased cellular destruction. The condition is more frequent in Caucasians than African Americans and is usually noted in childhood or adolescence. Since inheritance is autosomal dominant, patients can be screened and diagnosed at an early age.

The diagnosis is primarily made by evaluation of the red cell smear showing a large number of spherocytes. Spherocytes may also appear during autoimmune hemolytic anemias, but

in hereditary spherocytosis the Coombs test is negative and an osmotic fragility test may be performed, which is diagnostic. Also contributing to the diagnosis is a positive family history.

Patients with hereditary spherocytosis have mild to moderate anemia, splenomegaly, and jaundice. The patients may have intermittent flares of disease, which cause significant increased rates of hemolysis causing jaundice. Pigmented gallstones result in 30% to 60% of patients due to the breakdown of hemoglobin and clearance through the liver.⁸⁵

The treatment for hereditary spherocytosis is splenectomy, and this is indicated in virtually all patients.⁸⁷ This treatment does not remove the spherocytes, but it relieves all symptoms.⁸⁸ The major question involving management of these patients is the timing of splenectomy. Due to the increased incidence of overwhelming postsplenectomy sepsis in very young children, it is usually recommended that patients wait until after the age of at least 4 to 6 years prior to splenectomy. For younger patients who are very symptomatic and require splenectomy, partial splenectomies have been reported to be beneficial in relieving the abdominal symptoms and anemia and may be a useful alternative procedure until patients reach an age at which total splenectomy is safer.⁸⁹ Patients after partial splenectomies had regrowth of tissue but in the short term did not have recurrent anemia.⁸⁰ Patients should be assessed at the time of scheduling a splenectomy for the presence of gallstones, and a laparoscopic cholecystectomy should be performed if stones are identified.

Hereditary Elliptocytosis. Hereditary elliptocytosis is related to hereditary spherocytosis although the former is not as severe. For patients who are symptomatic, virtually all of the same observations regarding pathophysiology and treatment can be made as for hereditary spherocytosis. This disease is also inherited in an autosomal dominant pattern, and the defect is believed to be in spectrin. The predominant abnormality changes spectrin such that it exists as a dimer instead of a tetramer. This change leads to an alteration in membrane plasticity that creates cells that are more elliptically shaped instead of a biconcave disc.

The signs and symptoms caused in this disease are much more mild than in hereditary spherocytosis in that only 10% of patients have clinical manifestations of anemia, splenomegaly, and in some cases jaundice. The treatment recommendation for symptomatic patients is splenectomy, which may be performed with laparoscopic techniques and also cholecystectomy if gallstones are present.

Hereditary Nonspherocytic Hemolytic Anemia. This is a heterogeneous group of rare hemolytic anemias caused by inherited defects, primarily enzymes involved in glycolysis. These genetic defects may decrease cellular energy production such that during passage through the red pulp of the spleen, these patients may have cells that do not have the ability to produce ATP in a relatively hypoxic environment, leading to increased red cell destruction. The most common subtypes in this group of hemolytic anemias are pyruvate kinase deficiency and glucose 6-phosphate dehydrogenase deficiency (G6PD). Patients present with anemia, jaundice, increased reticulocytes, and sometimes cholelithiasis. Differentiation from spherocytosis and elliptocytosis can be made in that the shape of the cell does not show spherocytes and there is normal osmotic fragility.

The primary treatment for these diseases is blood transfusion. In G6PD deficiency, splenectomy is not usually beneficial though it may reverse some of the symptoms associated with pyruvate kinase deficiency.

Thalassemia. Thalassemia is an autosomal dominant disease with various structural defects in one of the globin chains. The disease is either alpha, beta, gamma, or delta thalassemia depending on which of the globin chains is defective. The vast majority of patients in North America have beta-thalassemia. Thalassemia major, otherwise known as Mediterranean

anemia or Cooley anemia, is a homozygous expression of this genetic defect. Thalassemia minor is heterozygous expression; these patients are only mildly symptomatic and are carriers for the more severe form of the disease.

The pathophysiology of thalassemia major or beta-thalassemia is the lack of production of normal beta-chain hemoglobin leading to a surplus of alpha-chain hemoglobin in adults. These excess globin chains precipitate in the cytoplasm and attach to the inner surfaces of cytoplasmic membrane, leading to poor passage of these cells through the splenic sinusoids. This intracellular inclusion then leads to increased destruction and over time causes significant splenomegaly due to this increased clearance of red cells.

The diagnosis is made by identifying microcytic hypochromic anemia with target cells and increase in reticulocytes on the peripheral smear. Protein electrophoresis shows very low levels of hemoglobin A with predominant amounts of the fetal hemoglobin, or hemoglobin F. The clinical symptom of alpha-thalassemia major is severe anemia within the first year of life. Decreased growth rate, enlargement of the head, splenomegaly, and hepatomegaly are the typical clinical findings.⁹⁰

The primary treatment for thalassemia major is frequent transfusions combined with iron chelation therapy. Some patients develop significant splenomegaly due to overload or hypertrophy from excess trapping of red cells.⁹¹ Patients may be referred for splenectomy for symptomatic splenomegaly or for massive and frequent transfusion requirements. One report suggested that episodes of transfusion are decreased from 18 per year down to 4 per year after splenectomy. In general, if there are symptoms of massive splenomegaly, these are resolved by splenectomy. As with other hematologic disorders in children, there has been a recent trend toward partial splenectomy, particularly in children younger than 4 to 5 years of age.⁹² This results in symptomatic improvement for 1 to 2 years with recurrent disease due to hypertrophy of the residual splenic remnant.⁹³

Although splenectomy may be beneficial in terms of the transfusion requirements and local symptoms, the typical mode of death with this disease is myocardial failure due to hemosiderin accumulation. Splenectomy does not alter this cardiac problem to any great extent. In fact, recent data suggest splenectomy in thalassemia patients increases vascular complications.

Sickle Cell Anemia. Sickle cell anemia is a hereditary hemolytic anemia due to a genetic alteration of a single amino acid in the beta chain. This results in a change from glutamic acid to valine in the sixth amino acid position of the beta chain of the hemoglobin molecule. Because of this substitution, patients who are homozygous for sickle cell defect have a characteristic stiffening or sickling of the red blood cells when the cells become hypoxic.⁹⁴ This change in red cell shape leads to blockage in hypoxic areas such as the red pulp of the spleen. There can occasionally be sequestration crises in which a portion of the blood volume gets actively trapped or sequestered to the spleen during the sickle cell crisis. This pattern of red cell shape change in relatively hypoxic areas can lead to tissue infarction with bone pain, hematuria, abdominal pain, or priapism.

Sickle cell anemia occurs almost exclusively in the black population, and the incidence of homozygous disease is approximately 0.5%, though approximately 8% of African Americans are carriers for the sickle cell trait. Patients who have a combination of a sickle cell allele as well as a beta-thalassemia allele manifest a similar disease process.

The clinical signs of the disease usually present during the second 6 months of life. In early infancy the patient is asymptomatic due to the presence of fetal hemoglobin. Patients may have acute crises with abdominal pain and bone pain in conjunction with significant anemia. During acute crises of splenic sequestration, there can be massive enlargement of the spleen and an urgent decompressive splenectomy can be required. Patients who do not need splenectomy for splenic sequestration

can be followed as this disease goes through a natural progression of ischemic necrosis of large areas of the spleen with eventual hyposplenism with a shrunken organ by early adolescence. Splenectomy is reserved for the very young patients who have massive splenomegaly during sequestration crises early in life.

Wiskott-Aldrich Syndrome. Wiskott-Aldrich syndrome is an X-linked disease characterized by thrombocytopenia, combined B- and T-cell deficiency, eczema, and a propensity to develop other malignancies. The genetic defect in this disease is related to an abnormal adhesion molecule affecting immune cell interaction as well as platelet adhesion. Thrombocytopenia is the major problem with this rare disease, and most patients present at a young age with manifestations of poor clotting, bloody diarrhea, epistaxis, and petechiae. The platelet counts typically range between 20,000 and 40,000, and the platelets that are present are 25% to 50% of normal platelet volume and dysfunctional. In this disease, the spleen sequesters platelets and partially degrades them releasing “microplatelets” back into the circulation.⁹⁵

Splenectomy in the Wiskott-Aldrich syndrome was initially avoided as there was a very problematic postoperative course characterized by severe and fatal infections due to the underlying immunodeficiency combined with the potential for overwhelming postsplenectomy infection. However, splenectomy does increase the number, size, and function of platelets and can lead to amelioration of the bleeding problems in very symptomatic patients.⁹⁵ The combination of splenectomy with antibiotic therapy may be beneficial, particularly in younger patients. The optimal treatment for Wiskott-Aldrich syndrome is an HLA-matched sibling bone marrow transplant.⁹⁶ However, splenectomy with antibiotics results in better survival than unmatched bone marrow transplantation. Patients who do not undergo bone marrow transplantation or splenectomy typically do not survive past the age of 5 years. The pathology of spleens removed for Wiskott-Aldrich syndrome show a near complete depletion of white pulp supporting the clinical immune deficiency seen in this syndrome.⁹⁷

Hypersplenism

- 8 Hypersplenism is a physical enlargement of the spleen that can occur due to neoplastic disorders, hematopoietic disorders of the bone marrow, and metabolic or storage disorders. In the neoplastic disorders, the spleen is infiltrated and enlarged by leukemia or lymphoma cells. This often happens in the mid or late course of the disease but can be associated with isolated splenomegaly in which splenectomy is performed not only to treat hypersplenism, but also to make the definitive diagnosis (see Diagnostic Splenectomy section later). Hypersplenism associated with diseases of hematopoiesis related to myeloid metaplasia in which the bone marrow is infiltrated with fibrotic material and the spleen becomes a site of secondary non-bone marrow hematopoiesis. Enlargement can lead to symptoms of hypersplenism due to the massive size of the spleen. Often the benefits of extramedullary hematopoiesis are outweighed by circulating blood cell destruction in this enlarged spleen. Secondary hypersplenism can also occur due to deposition of lipid within the spleen, such as in Gaucher disease, leading to enlargement that can cause pancytopenia. Each of these etiologies of secondary hypersplenism is associated with pancytopenia and mass effect of the spleen causing early satiety and weight loss. These disorders typically lead to spleen size greater than 1,500 g and can produce spleens that fill the entire left side of the abdomen.

Chronic Lymphocytic Leukemia. Chronic lymphocytic leukemia (CLL) is the most common of all chronic leukemias. It predominantly affects males with 2:1 gender predominance and has a peak incidence in the sixth decade of life. This indolent disease presents with fatigue, lymphadenopathy, hepatosplenomegaly,

FIGURE 73.10. A massively enlarged, 2.2-kg spleen from a patient with chronic lymphocytic leukemia. Superficial areas of infarction are indicated by *thin arrows* and splenic infarction by the *thick arrow*.

and eventually anemia and thrombocytopenia. Disease progression often occurs over a 5- to 10-year period.

Patients in stage II or greater CLL have splenomegaly and anemia and thrombocytopenia secondary to hypersplenism. Splenomegaly often reaches very large sizes, and patients may have symptoms secondary to the compressive effects of the large spleen on the stomach with early satiety and pain (Fig. 73.10). Treatment for early-stage disease is either observation or treatment with nontoxic doses of alkylating agents such as chlorambucil or cyclophosphamide. A newer agent that is frequently used is fludarabine. Medical therapy is never curative, and eventually the predominant symptoms are due to hypersplenism and splenomegaly. Splenic radiation has been used for patients who are nonoperative candidates.⁹⁸ Splenic radiation can decrease the size of the spleen, improving symptoms due to mass effect, but it can have complications of further thrombocytopenia and leukopenia.

Splenectomy is a highly successful treatment for both the pressure effects due to splenomegaly as well as the cytopenias.^{99–101} Published reports include 85% resolution of thrombocytopenia and 100% resolution of anemia.¹⁰² The negative feature of splenectomy in this patient population is that they are typically elderly and debilitated from having gone through years of having CLL and prior chemotherapy treatment. In one series in which a prospective comparison was made between splenectomy and fludarabine for later-stage CLL, there was a 9% perioperative mortality in the splenectomy group primarily due to sepsis.¹⁰³ However, in this same study, there were highly significant improvements in thrombocytopenia and anemia. The patients who are younger and have larger spleens tend to do better. In this comparative study, patients with Rai stage IV CLL had a 55% survival in the splenectomy arm and a 29% survival in the fludarabine arm. At present, splenectomy is recommended for patients who have failed medical therapy and have anemia with transfusion requirements, thrombocytopenia with bleeding, or compressive symptoms such as splenomegaly.

Chronic Myelogenous Leukemia. Chronic myelogenous leukemia (CML) is a leukemia with a primitive hematopoietic cell as the cell of origin. This precursor cell can differentiate into myeloid cell lines, erythroid cell lines, platelet cell lines, and possibly B lymphoid and T lymphoid cells. CML occurs preferentially in men to women at a 1.5:1 ratio and, like CLL, typically occurs in the sixth decade of life or older. This disease varies from CLL in that it invariably progresses from a chronic stage to an accelerated (blast) stage whereas CLL remains more indolent. The initial chronic phase lasts between 1 and 5 years and is characterized by splenomegaly, constitutional symptoms of fatigue, abdominal fullness, and weight loss.¹⁰⁴ The accelerated phase is apparent with 15% of circulating cells being more immature blast cells. Within 3 to 6 months this generally converts to the terminal blast phase in which the blastic cells fill the bone marrow and the circulating blood at greater than 30% of leukocytes and cause destruction of other organs. Death due to infection or bleeding invariably results after the blast crisis begins.

The diagnosis of CML is made by the leukocytosis with myeloid differentiation and presence of granulocytes filling the bone marrow space. Ninety percent of patients have the classic Philadelphia chromosome, which is a reciprocal translocation between chromosomes 9 and 22. On the basis of randomized trials, there is no benefit in terms of delaying the accelerated and blast phases of the disease by doing a splenectomy during the chronic phase of the disease. Certain select patients who have significant hypersplenism or splenomegaly may have symptomatic benefit from splenectomy during the chronic phase.^{105,106}

A recent study from M.D. Anderson Cancer Center reports their experience of splenectomy during the accelerated or blast phase of disease.¹⁰⁷ Patients were referred for this procedure with symptoms of splenomegaly in 42% of cases, thrombocytopenia in 30% of cases, to potentially improve administration of chemotherapy by reducing the hypersplenism in 19% of cases and because of symptoms with both hypersplenism and thrombocytopenia in 9% of cases. The perioperative mortality in this series of 55 patients was 2% (one patient death).⁹³ There was universal benefit of symptoms related to splenomegaly, and there was a marked improvement of platelet count and requirement for platelet transfusions in patients with preoperative thrombocytopenia. The median 6-month transfusion requirement decreased from 21 down to 1 (both platelet and red cell transfusions). The median post-splenectomy survival was 19 months for patients in the accelerated phase and 6.5 months for patients in the blastic phase of their disease. This report concludes that for select patients who have severe transfusion requirements and/or severe symptoms of splenomegaly, there is objective benefit with relatively low morbidity in patients with this later stage of CML.

Non-Hodgkin Lymphoma. Non-Hodgkin lymphoma (NHL) is the most common lymphoma, outnumbering Hodgkin disease by a ratio of almost 6:1 in the United States. Non-Hodgkin lymphoma is a much more heterogeneous disease with a large range of histologic cell types defined by morphology and immunohistochemistry to differentiate subgroups of the disease. The clinical course of these subgroups correlates with the microscopic findings. In general, diffuse or infiltrative non-Hodgkin lymphoma has a worse prognosis than nodular NHL. The diffuse high-grade type occurs most commonly in the younger patient population (age <35 years) or the very elderly. More aggressive non-Hodgkin lymphomas are T-cell lymphomas, whereas the low-grade tumors are usually B-cell. Non-Hodgkin lymphoma presents in approximately one third of cases at extranodal sites, whereas two thirds are limited to lymphadenopathy.^{108,109} In general, the disease is more diffuse at the time of presentation, mandating treatment by combination chemotherapy.

In patients dying of NHL, up to 80% have significant splenomegaly due to lymphatic infiltration.^{110,111} As is true

FIGURE 73.11. Spleen from a patient with hairy cell leukemia. Note the whitened anterior edge of the spleen and the white “sugar-coating” spots on the surface.

with other infiltrative neoplastic diseases, symptoms of pancytopenia and splenomegaly are common in patients with NHL. Patients who are operative candidates have significant benefit with up to 80% of patients having decreased transfusion requirements and most patients having relief of gastric oppression and pain symptoms due to splenomegaly.¹¹² The response of the pancytopenias is somewhat dependent on the bone marrow reserve, which may be altered by prior chemotherapy and/or radiation therapy. There is no test to identify adequate marrow reserve, and the only assessment in that situation is whether a patient has a response following splenectomy.

Hairy Cell Leukemia. Hairy cell leukemia is a low-grade lymphoproliferative disorder with characteristic “hairy” cells due to irregular filament projections from the cell surface visible under light microscopy.¹¹³ This leukemia is a B-lymphocyte tumor that infiltrates the bone marrow and spleen with almost no peripheral lymphadenopathy. There may be enlargement of the liver. The disease is much more common in males than females by a fourfold difference, and the onset of disease is typically in the fifth or sixth decade of life.

The initial symptoms most commonly relate to enlargement of the spleen either by direct effects of splenomegaly or by pancytopenia due to hypersplenism (Fig. 73.11).¹¹⁴ Patients can have early satiety or upper quadrant pain with a large palpable spleen infiltrated with leukemic cells. The enlarged spleen often causes symptoms related to anemia with a transfusion requirement, bleeding due to thrombocytopenia, and frequent infections due to leukopenia. In the past, hairy cell leukemia was described as the “surgical leukemia” as splenectomy was recommended as the primary treatment, and virtually all patients had resolution of symptoms of splenomegaly. Thus, splenectomy was the standard of care.¹¹⁵ However, the vast majority of patients relapsed, some as early as 6 to 12 months later, and only 40% to 50% of patients received long-term benefit from the cytopenias due to bone marrow replacement with hairy cell infiltrates.

In 1984, medical therapy led to responses, initially with recombinant alpha-interferon.¹¹⁶ Newer trials with purine analogues such as pentostatin (2-deoxycoformycin) and 2-chlorodeoxyadenosine provided a beneficial nonsurgical therapy.¹¹⁷ A randomized trial comparing pentostatin with α -interferon showed a complete response rate of 78% with pentostatin versus 11% with α -interferon, and this has now become a first-line therapy.¹¹⁸ The 10-year survival rate for pentostatin was 96%

and 100% for Cladribine.¹¹⁹ Five percent to 10% of patients who are resistant to medical therapy should be offered splenectomy as a salvage therapy.

Myelodysplastic Syndrome. Agnogenic myeloid metaplasia (AMM) or myelodysplastic syndrome (MDS) with myeloid metaplasia is a poorly understood disorder characterized by a fibrotic replacement of the bone marrow compartment with extramedullary hematopoiesis and massive splenomegaly.¹²⁰ The pathophysiology of the disease is poorly understood but includes a nonclonal proliferation of fibroblasts making a dense fibrous stroma that fills the marrow space and contributes to hepatosplenomegaly and lymphadenopathy. This fibrous proliferation may be under control of secreted growth factors such as transformin growth factor-beta.¹²¹ Other myeloproliferative diseases include polycythemia vera and essential or idiopathic thrombocytosis.

The clinical symptoms and features of MDS relate to anemia and splenomegaly via direct mass effects or hypersplenism.¹²² Patients are usually in the fifth decade of life or older. They present with constitutional symptoms including weight loss and fatigue, as well as abdominal fullness and discomfort due to splenomegaly. Splenic infarctions can cause pain. Patients may present with bleeding due to thrombocytopenia. Hepatomegaly is present in 50% to 75% of patients, and splenomegaly is present in virtually all patients. The massively enlarged spleens in MDS are some of the largest spleens by weight in most clinical series.

The combination of massive splenomegaly with increased blood flow via the enlarged spleen and hepatomegaly with fibrosis can lead to relative portal hypertension. Clinical symptoms may be similar to portal hypertension from other causes including varices and ascites. The diagnosis is made by evaluation of peripheral blood smear that shows immature red cells with poikilocytes and tear-shaped cells. There can either be thrombocytopenia or thrombocytosis with platelet counts of greater than one million. Similarly, there may be leukopenia or elevated white cell counts similar to CML. Bone marrow biopsy often produces a hypocellular sample due to the fibrotic replacement of the marrow space.

Treatment is generally targeted to palliate symptoms.¹²² Anemia and thrombocytopenia can be treated with transfusions. There is some role for alkylating agents and steroids, and in patients with thrombocytosis, hydroxyurea is of benefit.¹²³ Splenectomy is indicated for relief of significant symptoms of hypersplenism or splenomegaly.¹²⁴ Hypersplenism is manifested by anemia and thrombocytopenia with increasing transfusion requirements. Patients who have significant pain and early satiety with massively enlarged spleens may benefit by removal of mass effect. Finally, MDS is a unique situation in which splenectomy may treat portal hypertension, decreasing variceal bleeding and possibly ascites.¹²⁵

The Mayo Clinic has updated use of splenectomy over the past three decades for patients with myelofibrosis.¹²⁶ A total of 314 patients have been treated overall with 91 patients treated during the last 10 years. The primary indications for surgery were mechanical symptoms of compression due to massive splenomegaly in 49%, severe anemia in 25%, portal hypertension in 15%, and thrombocytopenia in 11%. The meaningful improvement in symptoms was observed in 30% to 50% of patients, but the overall complication rate was 28% and there were 6.7% perioperative deaths.¹²⁶ Furthermore, there is no clear overall impact on patient survival, disease course, or the intramedullary manifestations of myeloid metaplasia after splenectomy. Given these results, all factors including severity of symptoms and comorbidities must be considered before recommending splenectomy for this hematologic disorder.

Treatment strategies have changed in MDS in the past 5 years. One new therapy is antiangiogenic therapy, and the other is immunosuppressive treatment.¹²² There is an increase

in neovascularity of the bone marrow in patients with MDS, and vascular endothelial cell growth factor appears to play a prominent role in pathophysiology. Specific antiangiogenic therapy to block vascular endothelial growth factor (VEGF), including the recently reported trial of thalidomide, led to independence from transfusions in a subgroup of patients with MDS. Interest in immunosuppressive therapy in MDS occurred because the subset of these patients with refractory anemia has autoimmune pathophysiology. Young patients or patients with HLA-DR 15 appear to have autoimmune etiology and have responded to immunosuppressive therapy. A new treatment includes JAK2 inhibitors, as the 63% of myelodysplasias patients with a JAK mutation have a much higher incidence of splenomegaly.¹²⁷

Metastatic Disease to the Spleen. The incidence of splenic metastases in autopsy studies of patients succumbing to malignancy ranges between 2.3% and 7.1%.¹²⁸ It is rare that splenic metastatic lesions are isolated disease. This can occur in colon cancer and ovarian cancer. In patients who have multiple areas of intra-abdominal malignancies, the most common histologies are breast, lung, colorectal, ovarian, and melanoma. There can rarely be isolated metastasis that may be excised for increase in disease-free survival, particularly for colorectal cancer and melanoma.¹²⁹ Techniques to differentiate benign from malignant lesions include fine-needle aspiration biopsy, MRI with gadolinium contrast to assess enhancement patterns, and specific ultrasound techniques.¹³⁰

Metabolic or Infiltrative Diseases. Gaucher disease is an autosomal recessive disorder with a deficiency in the lysosomal hydrolase, α -glucosidase, encoded by chromosome 1. Gaucher disease is the most common lysosomal storage disease. α -Glucosidase typically degrades sphingolipids like glucocerebroside. There is a markedly increased incidence of this disorder in Ashkenazi Jews. There are three types of this disease. Type I, the adult form, composes 99% of cases and is the one in which splenectomy was useful in the past. The defect in the acid α -glucosidase causes an accumulation of undegraded glycolipids that are taken up by the reticuloendothelial cells and result in infiltration of the spleen, liver, and bone marrow. The most common symptoms of this disease relate to hypersplenism as well as direct effects of massive splenomegaly. Thrombocytopenia with bleeding problems or anemia causing fatigue are the most common effects of hypersplenism. Patients also may have such massive spleens that they have early satiety and weight loss due to gastric compression.

The diagnosis can be confirmed by the measurement of acid α -glucosidase activity in peripheral white blood cells or cultured fibroblasts. Now that the genetic abnormality is known, patients can be screened by molecular techniques to identify carriers. Prenatal diagnosis is also available by amniocentesis or chorionic villous sampling.

In the past, treatment has included supportive care with platelet transfusions as well as erythrocyte transfusions. Splenectomy was frequently performed for advanced cases, and in this disease a significant experience with partial splenectomy was developed in the early 1990s.¹³¹⁻¹³³ The goals of the subtotal splenectomy are partially to prevent the complications of overwhelming postsplenectomy sepsis and to partially protect the liver and bone marrow by leaving a residual splenic fragment for continued deposition of lipid. In this disease, the technique to safely perform partial splenectomy leaves a small residual upper pole fragment vascularized from the short gastric vessels.

Recently, it has been established that enzyme replacement with purified placental acid α -glucosidase is safe with good efficacy. Patients receive enzyme intravenously, 30 to 60 units per kg every other week, and the symptoms and signs are typically reversed. A recombinant α -glucosidase (alglucerase) is

now available for therapy, and the role of splenectomy has been displaced by medical management.

INCIDENTAL SPLENECTOMY

In a large series evaluating reasons for splenectomy from Barnes Hospital and Brigham and Women's Hospital, the single most common indication for removing the spleen was incidental during a procedure for nonsplenic pathology.^{37,38} This was primarily because removal of an adjacent organ or tumor required removal of the spleen either for completeness of resection or because of removal or ligation of the splenic vasculature. In this large series, more than 26% of the splenectomies performed over a 10-year period were incidental splenectomies (Table 73.7).³⁷ The actual primary treatments of those various disease entities in adjacent organs are subjects of multiple other chapters within this textbook, but a few comments can be made regarding the reasons for splenectomy and whether it is always appropriate.

The one common indication for an incidental splenectomy is during removal of the distal pancreas. For decades, the standard procedure when a distal pancreatectomy was performed was to include a splenectomy. The reason for splenectomy is that the splenic vein is intimately associated with the undersurface of the pancreas and has many direct branches to the pancreatic parenchyma. The splenic artery generally is superior to the pancreatic border and could be preserved, but because of removal of the splenic vein and for completeness of the resection, an en bloc resection of the distal pancreas and spleen is typically performed. Because of the interest in splenic preservation due to the incidence of postsplenectomy infection, two different approaches have been used to remove the distal pancreas without removing the spleen. The more technically challenging operation is a distal pancreatectomy with preservation of the splenic artery and vein. This can be performed if there is a relatively small amount of invasive tumor or benign neoplasia in which the splenic vein can be dissected away from the pancreatic tissue, tying multiple side branches and then dividing the pancreatic parenchyma leaving the splenic vessels intact. The second spleen-preserving distal pancreatectomy involves ligation of the splenic artery and vein but preservation of short gastric vessels and using those vessels as collateral inflow and outflow to maintain splenic viability. A recent report demonstrated no increased risks of preoperative complications or morbidity with this approach.¹³⁴ Removal of the distal pancreas with splenic preservation has also been recently reported as a laparoscopic procedure as well.¹³⁵ For patients with tumors that mandate removal of the lymph nodes of the splenic hilum or with direct association of the tumor with splenic parenchyma, it is more appropriate to do an operation based on neoplastic principles and perform a distal pancreatectomy with splenectomy. In other indications, if the anatomy is appropriate and the completeness of tumor resection is not compromised by splenic preservation, it is certainly possible.

Additional procedures in which it is quite common to perform a splenectomy include proximal gastric cancers. The importance of complete nodal dissection in long-term results in gastric resections has been debated for several decades. A report from Japan noted that in 20% of proximal gastric cancers there were positive splenic hilum nodes identified as level X lymph nodes.¹³⁶ These authors emphasize the need to perform associated splenectomy for grossly positive nodal disease in the splenic hilum. A long-term retrospective review from Memorial Sloan-Kettering Cancer Center noted that in 23% of gastrectomies in which complete resection of cancer was accomplished, adjacent organs had to be removed, the most common being the spleen.¹³⁷ There was long-term survival in this patient population, but it was emphasized that this aggressive surgery should be used only when removal of all gross disease is achieved.¹³⁸ A recent randomized study from Korea

showed no benefit in doing a splenectomy if splenic hilum nodes were grossly normal.¹³⁹

Other tumors of the left upper quadrant and retroperitoneum that may require splenectomy include large renal cell carcinomas, left adrenal tumors, and retroperitoneal sarcomas that can infiltrate into the spleen. Often splenectomy is useful to provide adequate exposure to cleanly dissect bulky disease posterior to the spleen. Although the asplenic state does make patients susceptible to infections (see previous Hyposplenism), there should be no hesitation to remove the spleen in those settings to achieve the appropriate complete resection.

IATROGENIC SPLENECTOMY

An uncommonly discussed area of spleen surgery is removal or preservation of the iatrogenically traumatized spleen during unrelated abdominal operations. Procedures in which mobilization of the left upper quadrant such as reflection of the spleen and pancreas medially to expose retroperitoneal tissue, left adrenalectomy, and left nephrectomy put the spleen at risk.¹⁴⁰ Simple mobilization of the splenic flexure of the colon can lead to bleeding from the inferior pole of the spleen that can be difficult to control. The ligaments that go directly from the omentum to the capsule of the spleen are the most common cause of iatrogenic splenic trauma as retraction of the omentum for exposure can strip the splenic capsule from the organ. A national database on antireflux procedures of 86,411 patients reported an incidence of iatrogenic splenectomy of 2.3%, which is 1,987 iatrogenic splenectomies for that indication alone.¹⁴¹

Probably the best data for the incidence of iatrogenic splenectomy comes from the recently reported series from Vanderbilt, which listed 73 iatrogenic splenectomies over a 10-year period or an average of 7 per year.³⁸ This constituted 8.1% of all splenectomies performed during that time interval. There are likely more minor or moderate injuries to the spleen during unrelated operations in which the spleen was not removed but was repaired or salvaged. Just as in trauma to the spleen, the techniques of splenorrhaphy can be used to preserve the spleen. A recent report indicates that use of a mesh wrap splenorrhaphy even in the setting of bowel surgery does not lead to an increased incidence of infection.⁴³ For minor capsular disruption, the use of the argon beam coagulator for surface cautery is a helpful technique.

Two large recent reports have evaluated the incidence and effects of inadvertent splenic injury during colectomy. The Mayo Clinic surveyed 13,897 colectomies and found 59 splenic injuries (0.42%). Most of these occurred during mobilization of the splenic flexure.¹⁴² The 30-day morbidity rate for this subgroup of patients was 34%, and the mortality rate was 17%. There were no clear episodes of sepsis. A second large study from the California Cancer Registry of almost 42,000 patients showed that there was a similar rate of inadvertent splenectomy of 0.58%.¹⁴³ This was associated with a distal transverse colon or splenic flexure primary and increased the length of hospital stay by 37.4%. It also increased the probability of perioperative death to 40%.

The primary teaching point regarding iatrogenic injuries is that the best way to preserve the spleen is to not damage it in the first place. This requires caution in mobilizing tissue in and around the spleen as well as visual inspection of the attachments of the spleen prior to blunt mobilization. Whenever possible, the spleen should be preserved to decrease the risk of postsplenectomy sepsis.

DIAGNOSTIC SPLENECTOMY

Splenectomy is sometimes necessary for diagnosis in an otherwise asymptomatic patient. The situation in which splenectomy may be needed to make a diagnosis includes when a mass

lesion is identified within the spleen on CT scan, ultrasound, or MRI scan for which a definitive diagnosis cannot be made radiographically. Another example is when patients have either palpable spleens on physical examination or enlarged spleens by scan and otherwise have no clear disorder. Table 73.10 lists the final pathology diagnoses in spleens removed for these two indications over a 10-year period in two major academic medical centers.³⁷ In that series, a total of 122 diagnostic splenectomies were performed; 52 were for splenic mass, and 41 were for splenomegaly with no other clear diagnosis. An additional 29 were done to further characterize a known hematologic malignancy.

Of the patients who had an isolated splenic mass, 60% had malignant lesions and 40% had benign lesions (Table 73.10).³⁷ Most of the malignant lesions were lymphoma, with another large group of metastatic carcinomas including some in which the primary diagnosis had not been made previously. There were two patients with metastatic sarcoma to the spleen. Of the benign diagnoses, more than half were cysts and there were also splenic hamartomas and splenic hemangiomas.

In the diagnosis of an isolated splenic mass, most of these lesions could have been diagnosed by a fine-needle aspiration biopsy. Certain of these lesions such as the cystic lesions or the hemangiomas have a classic appearance on gadolinium-enhanced MRI scan, which can be used to sort out mass lesions without tissue biopsy. Although there may be some hesitation to do fine-needle aspiration biopsies on splenic lesions due to the risk of bleeding, for most mass lesions this would have made the diagnosis, and with the exception of splenic hemangiomas, essentially all of these lesions could be aspirated without any significant consequence.

The second diagnostic indication for splenectomy is unexplained splenomegaly. In this series over 10 years there were 41 cases, or 4 cases per year at these two hospitals in which a

massively enlarged spleen was removed purely for diagnosis.³⁷ Most of these (58%) turned out to be lymphoma. The remaining 42% were split relatively evenly between benign lymphoid proliferation, benign vascular lesions, and granulomatous disease, as well as splenic infarction and hemorrhage. The role of fine-needle aspiration and other percutaneous biopsies for splenomegaly is limited as there is considerable risk of bleeding for this indication, and there would be a very low yield in terms of being able to make that diagnosis by that form of biopsy.

Staging laparotomy for Hodgkin disease is a diagnostic procedure that is infrequently necessary in current practice. A standard practice for pathologic staging between 1960 and 1990 was performance of a staging laparotomy in most patients with Hodgkin disease. The reason to perform this invasive procedure was based on reports that laparotomy altered the clinical stage of disease in approximately 35% of patients. Of these patients, approximately two thirds, or 20% to 25%, were up-staged to a more advanced level by staging laparotomy, and approximately one third, or 10% to 15%, were down-staged to a lower clinical level based on laparotomy results. Since the treatment of Hodgkin disease depended on accurate staging (i.e., early stages were treated differently than more advanced stages), the staging laparotomy was essential in determining the proper therapeutic intervention for patients with Hodgkin disease.

Staging laparotomy was performed via an upper abdominal midline incision.¹⁴⁴ This included exploration of the entire abdomen for any abnormal lymph nodes, including nodes identified by lymphogram. Even if no abnormalities were found, multiple tissues were removed for pathologic assessment (Fig. 73.12). This included removal of the spleen, bilobar hepatic wedge resections, bilobar hepatic core biopsies, and multiple lymph nodes samplings. Lymph nodes were typically removed from the porta hepatis area, the celiac region, the splenic hilum, the periaortic region, and the bowel mesentery.

If any iliac lymph nodes were palpated, they were removed as well. The spleen removed during a staging laparotomy for Hodgkin disease was sliced at 3 to 4 mm thicknesses, and any suspicious nodule, particularly in the white pulp, was examined microscopically for the presence of Hodgkin disease.

There are several reasons why the incidence of performing staging laparotomy has decreased over the past two decades.¹⁴⁵ The primary reason is that it no longer alters treatment of Hodgkin disease. The treatment of patients with stages IB, IIB, IIIB, IVB, IIIA, and IVA Hodgkin disease almost always involves systemic chemotherapy. Accurate pathologic staging makes no impact on the treatment outcome or treatment decisions. The only patients who may theoretically benefit from staging laparotomy at present are patients with stage IA or IIA Hodgkin disease who typically may receive treatment with radiation therapy. Even in this subgroup of patients there is a trend toward not performing staging laparotomy. First, many oncologists use combination chemotherapy even for early stage disease. Second, for patients who were treated with radiation therapy alone for stage IA and IIA disease, it has been demonstrated in several recent clinical series that the ultimate outcome is equivalent whether these patients undergo staging laparotomy or whether they are treated initially with radiation therapy.^{146,147} The reason is that if these patients recur outside of the radiation field during long-term follow-up, salvage can be obtained with systemic chemotherapy. Third, performance of staging laparotomy is a major abdominal operation with potential for morbidity and the treatment for the Hodgkin disease must be delayed for 4 to 6 weeks. Finally, there are data that patients who survive Hodgkin disease and receive combination chemotherapy are at increased risk for the development of a secondary malignancy that is primarily acute, nonlymphocytic leukemia (ANLL).^{148,149} In some series, the risk of developing ANLL is increased up to tenfold in patients who have undergone splenectomy as part of their

FIGURE 73.12. The tissues to be removed or to undergo biopsy in a staging laparotomy for Hodgkin disease. Splenectomy, liver biopsy, and lymph node sampling in the specific sites are shown. Bone marrow biopsy can be done if necessary.

staging workup for Hodgkin disease compared to patients undergoing similar chemotherapy regimens who did not undergo splenectomy. For all of these reasons, this procedure that also accounted for a large number of the splenectomies performed in major tertiary referral centers and cancer centers is rarely performed now.

VASCULAR DISORDERS OF THE SPLEEN

Vascular problems with the spleen that can require splenectomy include both venous and arterial problems. The most common is splenic vein thrombosis; splenectomy in this setting is typically curative in sinistral portal hypertension. Splenic artery aneurysms are one of the more common visceral aneurysms and also can be an indication for splenectomy.

Splenic Vein Thrombosis

Splenic vein thrombosis is an unusual cause of upper gastrointestinal hemorrhage that can be cured by splenectomy. The pathophysiology of this disease is an isolated thrombosis of the splenic vein as it traverses along the posterior pancreatic body and tail. After thrombosis, splenic venous outflow is diverted to the short gastric vessels as the main collateral venous outflow. This increased flow via the short gastric veins leads to a high pressure with a dilatation of the submucosal venous plexus primarily in the gastric cardia and fundus and development of gastric varices.¹⁵⁰

The cause of the splenic vein thrombosis does not typically involve any pathology of the spleen, but rather, typically pathology of the pancreas and possibly the stomach. Pancreatitis or pancreatic pseudocyst is the cause of splenic vein thrombosis in more than 50% of patients in most series. Pancreatic carcinoma with direct invasion and infiltration of the splenic vein is the second most common cause. Other unusual causes may be a penetrating gastric ulcer posteriorly or retroperitoneal fibrosis.

The diagnosis is made in patients who have upper gastrointestinal bleeding with only gastric varices on endoscopy. Because there is no portal venous hypertension and no cirrhosis of the liver, there are no esophageal varices. The spleen may or may not be enlarged, but again there are no other signs and symptoms of cirrhosis. Definitive diagnosis in the past has been made by a celiac angiogram, which demonstrates absence of the splenic vein with collateral flow via the gastric veins. MR angiograms/venograms as well as high-resolution ultrasound can also make the diagnosis.

Splenectomy is curative as it removes the blood flow via the splenic artery through this organ. This removes all the excess collateral flow that leads to the venous hypertension, and the associated symptoms resolve. Whenever splenic vein thrombosis is diagnosed, even if the patient has not had an episode of bleeding, elective splenectomy should be performed as a prophylactic measure.

Patients with portal hypertension and cirrhosis or partial vein thrombosis have a complex collection of symptoms that include hypersplenism with splenomegaly, thrombocytopenia, and anemia. However, the operative risk associated with portal vein hypertension is excessive, and splenectomy is virtually never indicated in this setting.

Splenic Artery Aneurysm

Splenic artery aneurysm is uncommon, though it is the second most frequent abdominal artery to undergo aneurysmal changes.¹⁵¹ Splenic aneurysms occur twice as often in women as in men. Patients can be divided into two distinct groups. First,

there are elderly patients whose aneurysms are manifestations of atherosclerosis. Second, some young women have an apparent congenital predisposition to form splenic artery aneurysms. In these women, there is an increased risk of rupture of these aneurysms during pregnancy. Inflammatory processes such as pancreatitis may involve the splenic artery and occasionally lead to aneurysm but more frequently lead to acute bleeding.

Splenic artery aneurysms are typically asymptomatic and may be initially identified as a widened rim of calcification in the left upper quadrant defining the aneurysm boundaries. They may also be discovered as incidental findings on CT scan. If symptomatic, patients experience left upper quadrant pain, nausea, and vomiting. The presence of symptoms suggesting pending aneurysmal rupture indicates urgent splenectomy with ligation of the splenic artery.

When a calcified atherosclerotic splenic artery aneurysm is discovered in a patient older than 60 years of age with no splenomegaly and no symptoms, surgical excision is not indicated and the aneurysm may be followed for evidence of enlargement. In younger patients who have an asymptomatic aneurysm identified, particularly young women of childbearing age, an elective splenectomy is recommended to prevent rupture. Non-surgical approaches include embolization of the splenic artery in patients who are poor risks for open laparotomy.¹⁵²

MISCELLANEOUS INDICATIONS FOR SPLENECTOMY

Splenectomy is performed relatively infrequently for a miscellaneous collection of indications including splenic cysts, infectious cysts, and splenic abscesses. The wandering spleen is a normal spleen that lacks ligamental attachments to keep it in the left upper quadrant. This can present in various ways from an undiagnosed mass to torsion of the splenic hilum causing acute pain.

Cysts of the Spleen

Splenectomy is performed as described previously often for hematologic malignancies including multiple forms of leukemias and lymphoma, primarily for symptoms of hypersplenism or splenomegaly or as a staging procedure. Splenectomy for primary neoplasms of the spleen is an infrequent indication. These primary neoplastic processes are listed in Table 73.11.

Hemangioma is the most common benign primary neoplasm of the spleen. It is often an incidental finding and may be solitary or multiple. During operation, it can be identified as a more intensely bluish-purple colored lesion when seen from the surface compared to the reddish-purple color of the splenic parenchyma. The hemangiomas can be identified with excellent sensitivity and specificity by MRI characteristics. It is not advised to biopsy a lesion that may be a splenic hemangioma.^{153,154} Hemangiomas of the spleen rarely cause symptoms, but massive

hemangiomas can either rupture spontaneously or make the spleen more susceptible to a traumatic rupture. In cases of massive hemangioma with capsular distention and pain, either a splenectomy or partial splenectomy may be helpful.

Hemangioendothelioma is a slightly more aggressive neoplasm than the typical benign hemangioma. Pathologically it is an intermediate benign hemangioma and malignant angiosarcoma. It does not seem to have metastatic potential and generally is an incidental finding. Larger lesions can cause symptoms or be noted for their size and rupture either spontaneously or with minor trauma.

Lymphangiomas also occur in the spleen and are much less common than hemangiomas. They can be multiple or solitary and can be identified by a lighter color and compressibility when seen in surgery.

Two mass lesions that occur in the spleen that are not true neoplasms are hamartomas and inflammatory pseudotumors. Hamartomas are focal developmental abnormalities that occur in spleen and other solid organs such as the liver. Hamartomas contain normal cellular elements and are nonneoplastic but have a random fibrotic organization.¹⁵⁵ The major significance of hamartomas is that they are identified either at laparotomy as incidental findings or they are seen as incidental lesions on CT scans done for other reasons.¹⁵⁶ Inflammatory pseudotumors are described throughout most organs and have also been described in the spleen. These sometimes are quite large with a wide variety of reactive cells. A subcategory of inflammatory pseudotumors of the spleen are related to mycobacterial infection, particularly in HIV-positive patients. There have been reports of primary splenic pregnancy, which is considered the rarest site of ectopic pregnancies.

Cysts of the spleen are almost uniformly unrelated to parasitic infection. They are also relatively common lesions seen across all age groups and may be multifocal. The diagnosis of splenic cysts can be ascertained by ultrasound or CT scan. These benign lesions have no clinical significance unless they reach a large size. The first reported case of a successful elective splenectomy was done for a splenic cyst. This was an enormous cyst at the tip of the spleen and was believed to be an ovarian mass and found to be arising from the spleen at laparotomy (Fig. 73.13). Today a cyst enucleation or partial splenectomy for peripheral cystic lesions that are large and symptomatic would be sufficient. An alternative approach is unroofing the cyst and leaving a portion of the cyst wall in place; this can be done laparoscopically.¹⁵⁷

The only parasitic cyst involving the spleen is from *Echinococcus granulosus* or a hydatid cyst. The incidence of

echinococcal cyst in the spleen compared to the liver is a ratio of approximately 30:1. However, the spleen is the third most common site of echinococcal cysts behind the liver and lung.¹⁵⁸ Diagnosis should be suspected in patients in areas where echinococcal disease is common such as New Zealand, Australia, and parts of the western United States. The complement fixation test is the most reliable serologic study for this organism. The treatment of echinococcal cysts can include splenectomy. As with echinococcal cysts of the liver, it is of utmost importance not to rupture the cyst and expose the patient to the scoleces. For large and peripheral cysts in which risk of rupture is high, the contents of the cyst should be carefully aspirated and replaced with hypertonic saline.¹⁵⁹ In a recent report from Greece, surgeons preserved 8 of 19 spleens with echinococcal cysts by doing partial splenectomy.¹⁵⁸

Abscess of the Spleen

Splenic abscess is an uncommon but important disease because it is associated with a significant mortality rate and may be cured by splenectomy.¹⁶⁰ In most series, the mortality rate ranges between 40% and 100%.¹⁶¹ The typical patient has hematogenous seeding of the spleen by bacteria from a remote source such as endocarditis or from intravenous drug abuse.¹⁶² There may be in some cases direct spread of infection from adjacent intra-abdominal sources. Finally, splenic trauma treated conservatively may eventually result in an infected splenic hematoma. In 80% of cases, there is an additional source of infection in locations other than the spleen, and in only 20% of cases is the splenic abscess the sole source of sepsis identified. Enteric organisms account for two thirds of the splenic abscesses and staphylococcus and streptococcus cause the remainder of the cases.

The patients present with signs and symptoms of sepsis including fever, malaise, and leukocytosis. When the spleen is the sole site of infection, patients have significant left upper quadrant tenderness and guarding. Abdominal X-ray views may show gas in the spleen, and an ultrasound or CT scan with contrast can be diagnostic to show an abscess with reactive rim.

Splenectomy is the treatment of choice for patients who can undergo a laparotomy and who have the splenic abscess as an isolated or prominent component of septic syndrome. If the spleen is the only site of infection, removal of the spleen should be curative and result in the recovery of the patient. If patients have multiple sites of infection or are too sick to undergo laparotomy, percutaneous drainage of splenic abscesses may be attempted, but this is often not successful because of spillage and accumulation of infection in the left upper quadrant of the abdomen.

Ectopic Spleen (Wandering Spleen)

Ectopic spleens, or the so-called wandering spleens, occur because of either extreme laxity or absence of the normal ligaments that attach the spleen to the left upper quadrant. This allows the spleen to drop to the lower abdomen in either the right lower quadrant or left lower quadrant by the force of gravity, though still attached by its vascular pedicle.¹⁶³ This condition of a wandering spleen occurs thirteen times more frequently in women than in men. The wandering spleen presents most commonly in adults but can cause symptoms in children.¹⁶⁴ The diagnosis may be made by palpable lower abdominal mass confirmed by CT scan or a nuclear imaging spleen scan finding of splenic tissue. The ectopic spleen creates symptoms typically when there is torsion of the pedicle causing acute ischemia and acute pain. The treatment for a wandering spleen as an incidental finding at laparotomy or if the torsion can be corrected and the spleen appears to be viable is to do a splenopexy, affixing it to its native position in the left

FIGURE 73.13. The visceral surface of a spleen with a true congenital splenic cyst.

upper quadrant. If the spleen is infarcted, a splenectomy must be performed.¹⁶⁵ The wandering spleen is ideally suited for laparoscopic splenectomy as it is generally free from ligaments or attachments to other organs.¹⁶⁶

SPLENECTOMY

The choices of operations available currently to approach the spleen in an elective manner are open splenectomy, laparoscopic splenectomy, or partial splenectomy. Table 73.12 lists indications for splenectomy and whether a partial splenectomy is indicated. Certain principles apply to all patients undergoing elective splenectomy. First, all patients should receive appropriate preoperative vaccination with Pneumovax and possibly also vaccination against *Haemophilus influenza* and *Neisserian meningococcus* 10–14 days prior to the procedure if possible. Patients must have appropriate blood products ready as often patients are anemic and thrombocytopenic due to hypersplenism.

The operative technique for open splenectomy involves either a midline abdominal incision or a left subcostal incision. For patients with massive splenomegaly, defined as greater than 1,500 g in adults and greater than 1,000 g in children, a long midline incision should be used.¹⁶⁷ The components of the splenectomy include division of the avascular lateral and posterior attachments to mobilize the spleen, ligation of the short gastric vessels separating the upper half of the spleen from the greater curvature of the stomach, and ligation of splenic hilar vessels in a controlled manner to avoid injury to the pancreatic tail. One approach, particularly for small spleens that are

FIGURE 73.14. Lateral mobilization permits the spleen to reach the surface of a midline wound despite the presence of intact hilar vessels.

mobile, is to initially divide the lateral attachments and place packs in the left upper quadrant to elevate the spleen and then proceed with the vascular dissection (Fig. 73.14), but this should be discouraged particularly in patients who are thrombocytopenic or patients with massive splenomegaly. In this situation,

TABLE 73.12

OPERATIVE INDICATIONS FOR SPLENECTOMY

■ DISEASE	■ NEED FOR SPLENECTOMY	■ PARTIAL SPLENECTOMY
Hereditary spherocytosis	Always	Yes
Hereditary elliptocytosis	Sometimes	Yes
Thalassemia	Sometimes	Yes
Sickle cell anemia	Rarely	No
Wiskott-Aldrich	Sometimes	No
Autoimmune hemolytic anemia	Usually	No
Autoimmune neutropenia	Sometimes	No
Immune thrombocytopenia purpura	Usually	No
Thrombotic thrombocytopenia purpura	Sometimes	No
Hairy cell leukemia	Rarely ^a	No
Chronic lymphocytic leukemia	Sometimes	No
Chronic myelogenous leukemia	Sometimes	No
Non-Hodgkin lymphoma	Sometimes	No
Angiogenic myeloid metaplasia	Sometimes	Yes
Mastocytosis	Rarely	No
Gaucher	Rarely ^a	Yes
Hodgkin disease	Rarely ^b	No
Splenic vein thrombosis	Always	No
Splenic abscess	Usually	No
Splenic cyst	Rarely	Yes
Echinococcal cyst	Always	No

^aSplenectomy rarely indicated in current practice because of effective medical therapy.

^bSplenectomy rarely indicated because of change in current therapy.

the splenectomy should start by obtaining vascular control before manipulating the spleen and leading to capsular tears and significant blood loss.

The preferred operative approach in patients with splenomegaly¹⁶⁸ and hypersplenism is to first divide the attachments of the left lateral segment of the liver and retract this to the right side of the abdomen, exposing the greater curvature of the stomach. Then starting at the midportion of the greater curvature of the stomach, the branches of the left gastroepiploic artery and vein including short gastric vessels are ligated sequentially, completely dissociating the stomach from the superior portion of the spleen (Fig. 73.15). Through this window into the lesser sac created by dissecting the short gastric vessels, the splenic artery can be identified at variable locations along the superior border of the pancreas. A loop of this tortuous artery at its most superior or cranial portion is safest as at those points it is farthest away from the splenic vein as well as away from pancreatic parenchyma. The artery may be simply ligated once or twice with heavy silk ties at that location and does not need to be divided. By dividing short gastric arteries as well as ligating the main splenic artery, the vast majority if not all of blood flow into the spleen is controlled prior to even touching the spleen to mobilize it. If capsular disruption occurs, the amount of blood loss then is greatly minimized. Following vascular control, the lateral and posterior attachments are divided and the spleen is elevated to near the level of the abdominal wall musculature ventrally. The splenic hilum can then be dissected, tying vessels in a controlled manner.

For patients with ITP, platelets should not be given until the spleen is either removed or at least until the arterial inflow is controlled, because of clearance of transfused platelets by the spleen in this disease. Similarly, for this disease as well as other diseases in which the spleen is the site of platelet or blood cell destruction, it is important to identify and remove accessory spleens. Most of the accessory spleens occur in the splenic hilum, though they can also occur in the omentum, along the superior border of the pancreas, in the bowel mesentery, and in the pelvis in some situations. The incidence of accessory spleens identified during open splenectomy is between 15% and 30%.

Partial splenectomy can be performed based on the segmental blood supply to the spleen. The spleen is mobilized with good visualization. The inferior segmental arteries are generally ligated, and the artery and veins are ligated as a predemarcation of blood flow to the spleen. The splenic parenchyma is then transected, and the cut surface bleeding can be controlled using materials that induce coagulation or the argon beam coagulator.^{169,170}

For the past 5 to 10 years, the standard approach for an elective splenectomy in most large centers has become a laparoscopic approach.^{36,171,172} Even patients with massive splenomegaly can now have laparoscopic splenectomy with use of a hand port. In one recent series, there were no conversions in 16 consecutive patients with massive splenomegaly.¹⁷³ Another series noted a higher incidence of conversion to an open procedure when the spleen has weighed more than 2,000 g.¹⁷⁴

The technique of laparoscopic splenectomy begins with the patient either supine with a roll under the hip to prop the left side of the abdomen up approximately 30 degrees, or in the lateral decubitus position. The omental, inferior attachments and the short gastric vessels are divided, often with a powered dissection instrument. It has been reported that careful exposure of the splenic hilum with the direct ligation of the vessels is a much safer technique than division of the hilum with staples without precise vessel dissection.¹⁷⁵ Once the vessels are ligated, the spleen is placed into a large plastic bag and brought to the most convenient port for careful morselization. This can allow removal of the spleen without having to enlarge the port incisions and without fracture and spillage in the abdomen. Laparoscopic resection has extended to include massive splenomegaly¹⁷⁶ and partial splenectomy.¹⁷⁷

FIGURE 73.15. Technique for elective splenectomy. **A:** The inferior pole is reflected laterally by the assistant's fingers, exposing the lower edge of the hilar peritoneal envelope. **B:** The hilar peritoneum is opened, here shown progressing from inferior to superior. **C:** Individual vessels are identified and suture ligated.

Virtually all indications for splenectomy can be approached laparoscopically.¹⁷⁸ Laparoscopic splenectomy has been reported for removal of the wandering spleen.¹⁷⁹ In this indication it is actually a much easier operation as the spleen is free and the hilum is exposed. Accessory spleens may be identified less frequently and consequently left in place more often with a laparoscopic approach. The use of lymphoscintigrams after failed splenectomy can identify accessory spleens. The removal of accessory spleens can be done laparoscopically as well; adding a hand port for palpation assists in this type of procedure.¹⁸⁰

Radiofrequency ablation is a new technique added to treatment of splenic disorders.^{181,182} Radiofrequency ablation was developed in the mid-1990s primarily to treat liver lesions. There are various commercial products that essentially destroy tissue indiscriminately by heating to 100°C. The largest experience is with either primary or metastatic tumors in the liver, but this has also been used in treatment of bone metastasis, kidney lesions, lung lesions, and breast cancer. Recent reports indicate that radiofrequency ablation probes can be used successfully as a minimally invasive technique to treat splenic disorders such as thalassemia. There also may be a role for radiofrequency ablation to treat trauma to the spleen as a way to control severe injuries.¹⁸²

CHAPTER 74 ■ BREAST DISEASE

TARI A. KING AND MONICA MORROW

KEY POINTS

- 1 Screening mammography reduces breast cancer mortality by 20% to 30% and increases the likelihood of breast-conserving surgery.
- 2 Needle biopsy is the preferred method of diagnosing both palpable and nonpalpable breast masses. A benign needle biopsy diagnosis of a clinically or mammographically suspicious mass is an indication for surgical biopsy.
- 3 The most common causes of pathologic nipple discharge are a solitary papilloma (60%) or duct hyperplasia (15% to 20%), followed by ductal carcinoma in situ in 5% to 20% of patients.
- 4 If aspiration of a breast cyst yields nonbloody fluid and the mass resolves, no further therapy is needed; whereas if the fluid is bloody, the palpable abnormality does not resolve completely, or the same cyst recurs multiple times, biopsy to exclude malignancy is required.
- 5 A dominant breast mass should not be dismissed as a cyst unless the diagnosis is confirmed by ultrasonography or aspiration of fluid.
- 6 Mutations in the susceptibility genes *BRCA1* and *BRCA2* are present in 5% to 10% of women with breast cancer. They should be considered in women diagnosed before age 40 years and those with a family history of two or more relatives in the same bloodline with breast cancer, or in the presence of breast and ovarian cancer, bilateral breast cancer, or male breast cancer in the family.
- 7 The use of tamoxifen for 5 years in high-risk pre- or postmenopausal women results in an approximately 50% reduction in risk for invasive and noninvasive breast cancer.
- 8 The use of raloxifene in postmenopausal women for 5 years has a similar effect and fewer side effects.
- 8 Improvements in local control rates of greater than 10% at 5 years through the use of radiotherapy after lumpectomy or mastectomy are associated with improved breast cancer-specific and overall survival at 15 years.
- 9 There is no difference in survival for patients with invasive breast cancer treated with mastectomy and those treated with lumpectomy and radiotherapy.
- 10 For breast-conserving therapy to be successful in the treatment of invasive breast cancer, three conditions must be met. It must be possible to (a) reduce the tumor burden to a microscopic level likely to be controlled by irradiation, (b) safely deliver radiation therapy, and (c) promptly detect local recurrence.
- 11 Radiation therapy leads to an approximately 75% reduction in local recurrence after breast conservation therapy. Subgroups of women with invasive cancer not requiring radiation, other than women over age 70 with small, estrogen receptor-positive tumors, have not been reproducibly identified.
- 12 Regardless of the technique of sentinel node biopsy used, a sentinel node will be identified in 95% of breast cancer patients and will predict the status of the remaining axillary nodes in about 90% of cases.
- 13 Locally advanced breast cancer includes T3 and T4 tumors, those with extensive regional nodal involvement (N2 or N3), and inflammatory breast cancer, and should be treated with a combination of induction chemotherapy, surgery, and postoperative radiation therapy.

ANATOMY

The adult female breast lies between the second and sixth ribs and between the sternal edge and the midaxillary line (Fig. 74.1). Breast tissue frequently extends into the axilla as the axillary tail of Spence. Posteriorly, the upper portion of the breast rests on the fascia of the pectoralis major muscle; inferolaterally, it is bounded by the fascia of the serratus anterior. Bands of fibrous tissue, known as *Cooper ligaments*, extend from the fascia to the fibrous tissue of the dermis and support the breast. The size of the adult female breast varies widely among individuals, and there is considerable discrepancy in breast size between the breasts of an individual woman. This is rarely a sign of breast disease. The breast is composed of skin, subcutaneous tissue, and breast tissue. The breast tissue includes both epithelial parenchymal elements and stroma. The epithelial component comprises about 10% to 15% of the breast mass, with the remainder being stroma. Each breast consists of 15 to 20 lobes of glandular tissue that are supported by a framework of fibrous connective tissue. The space between

lobes is filled by adipose tissue. Variations in breast size are accounted for by differences in the amount of adipose tissue in the breast rather than the epithelial elements. Much of the epithelial tissue of the breast is found in the upper outer quadrant, which is why this is the most frequent site of both benign and malignant breast disease.

The lobes of the breast are subdivided into lobules, which are made up of branched tubuloalveolar glands. Each lobe ends in a lactiferous duct, 2 to 4 mm in diameter. Beneath the areola, the lactiferous ducts dilate into lactiferous sinuses and then open through a constricted orifice onto the nipple (Fig. 74.2).

The nipple is located over the fourth intercostal space in the nonpendulous breast and is surrounded by a circular, pigmented areola. Beneath the nipple and areola are bundles of radially arranged smooth muscle fibers that are responsible for the erection of the nipple in response to a variety of stimuli. The nipple and areola contain sebaceous glands and apocrine sweat glands, but no hair follicles. In addition, the tubercles of Morgagni are nodular elevations formed by the

FIGURE 74.1. The adult female breast. The upper and medial portions of the breast rest on the pectoralis major muscle, and the inferolateral portion rests on the serratus anterior.

openings of the Montgomery glands at the periphery of the areola. These glands are capable of secreting milk and are believed to represent an intermediate stage between sweat and mammary glands. The nipple and areolar region, as well as the remainder of the breast, is richly supplied with sensory innervation.

FIGURE 74.2. The breast consists of 15 to 20 lobes of glandular tissue. Within each lobe, the lobules are composed of branched tubuloalveolar glands. Each lobule ends in a lactiferous duct. These ducts dilate into lactiferous sinuses beneath the nipple.

The blood supply of the breast is derived from the internal mammary and lateral thoracic arteries. The medial and central portions of the breast receive their major blood supply from anterior perforating branches of the internal mammary artery, and the upper outer quadrant is primarily supplied by the lateral thoracic artery. In general, the venous drainage of the breast follows the arterial supply.

LYMPHATIC DRAINAGE

The lymphatics of the breast are thin-walled, valveless vessels that drain unidirectionally except when obstructed by inflammatory or neoplastic disease. The superficial subareolar lymphatic plexus drains primarily the skin of the breast and the nipple and areola, in addition to some of the central portion of the gland. This plexus is interconnected with the deep lymphatic plexus, which drains most of the breast parenchyma. Injections of radioactively labeled colloid have demonstrated that about 97% of the lymphatic flow from the breast drains directly into the axillary lymph nodes, with the remaining 3% draining into the internal mammary nodes.¹ All quadrants of the breast drain into the axillary nodes.

The axillary space is bordered by the axillary vein superiorly, the latissimus dorsi laterally, and the serratus anterior medially (Fig. 74.3). The pectoralis major lies anterior to the axillary space, and the subscapularis comprises its posterior wall. Structures of clinical importance within this space include the long thoracic nerve, which innervates the serratus anterior; the thoracodorsal neurovascular bundle, which innervates and supplies blood to the latissimus dorsi; and the intercostobrachial nerves, which are sensory to the upper inner aspect of the arm.

FIGURE 74.3. The axillary lymph nodes are divided into three levels by the pectoralis minor muscle. The level I nodes are inferior and lateral to the pectoralis minor, the level II nodes are below the axillary vein and behind the pectoralis minor, and the level III nodes are medial to the muscle against the chest wall.

The axillary nodes are embedded in fat and are variable in number. Surgeons have traditionally divided the axillary nodes into three levels: level I nodes, inferior and lateral to the pectoralis minor; level II nodes, behind the pectoralis minor and inferior to the axillary vein; and level III nodes, medial to the pectoralis minor and against the chest wall. The interpectoral (or Rotter) nodes are located between the pectoralis major and minor muscles along the lateral pectoral nerve. Involvement of this node group in the absence of axillary metastases is extremely rare,² and thus they are of limited clinical significance. The supraclavicular nodes are contiguous with the apex of the axilla. Metastatic involvement of this nodal group in the absence of extensive axillary disease is also uncommon, although direct lymphatic drainage to this node group occurs occasionally.

The internal mammary nodes are located in the first six intercostal spaces within 3 cm of the edge of the sternum. The highest concentration of internal mammary nodes is found in the first three intercostal spaces.³

PHYSIOLOGY

Development of the Breast

Breast development is controlled by a large number of hormonal and biochemical factors. In the female, estrogens interact with the primordial breast bud to promote ductal development, whereas in the male, the interaction of androgen with the breast bud results in destruction of the epithelial component. In the female, ductal elongation and branching begin in puberty and are regulated by pituitary growth hormone, which may act through insulinlike growth factor I locally.⁴ In addition, the presence of estrogen and progesterone is required to stimulate DNA synthesis. This effect is believed to occur through both receptor-mediated and paracrine pathways.

Changes in breast size and shape begin at puberty and are secondary to growth of both the glandular and stromal elements of the breast. Russo and Russo⁵ have described three types of breast lobules related to a woman's parity and menopausal status. The type 1 (or virginal) lobule consists of a cluster of 11 alveolar buds around a terminal duct; it is the predominant lobule in nulliparous and postmenopausal women. Type 2 lobules contain an average of 47 alveolar buds, and type 3 lobules have 80, at which time they are referred to as *ductules* or *alveoli*. In parous women, type 3 lobules predominate, with a peak frequency in the early reproductive years until they begin to decline in the fourth decade of life. Cells within these lobules have been shown to proliferate at different rates, the rate being 10 times higher in type 1 than in type 3 lobules, and three times higher in type 1 than in type 2 lobules. The presence of estrogen receptor- α (ER- α) and the progesterone receptor within these lobules is directly proportional to the rate of cell proliferation.⁶ These differences in cell proliferation may explain some of the differences in breast cancer risk observed on the basis of parity and age at first birth (see section on breast cancer risk factors).

The cyclic increases in estrogen and progesterone that occur in the menstrual cycle also influence the gross and microscopic character of the breast. Many women experience increased breast fullness, nodularity, and sensitivity in the premenstrual period. During the follicular phase of the menstrual cycle (days 4 through 14), epithelial proliferation occurs, with epithelial sprouting and an increased mitotic rate. During the luteal phase of the cycle (days 15 through 28), when progestins predominate, proliferation is maximal, with ductal dilation and differentiation of the alveolar epithelial cells to secretory cells. This results in the formation of lipid droplets in the alveolar cells and some intraluminal

secretion. With the onset of menstruation, secretory activity regresses secondary to epithelial apoptosis, or programmed cell death.

Pregnancy

Significant ductal, lobular, and alveolar growth occurs during pregnancy as a result of exposure to estrogen, progesterone, growth hormone, prolactin, and placental hormones. Clinically, this is manifested as breast enlargement, with associated dilation of the superficial veins and darkening of the nipple. At delivery, the breast may be three times the size of the nonlactating breast. Microscopically, lobular-alveolar differentiation to type 3 lobules begins in the first trimester, and the stromal elements of the breast are gradually replaced by the proliferating glandular epithelium. During the third trimester, terminal differentiation of the epithelium results in the development of secretory cells that are able to synthesize and secrete milk proteins. Oxytocin induces myoepithelial proliferation and differentiation.⁶

Lactation and Involution

After delivery, the sudden fall in estrogen and progesterone levels results in lactation. Prolactin, in conjunction with growth hormone and insulin, induces the production and secretion of milk. Initially, colostrum, a sticky serous fluid rich in growth factors, is secreted, followed by milk. Milk secretion is regulated by the pituitary production of oxytocin, which is released in response to neural reflexes activated by suckling.

Following weaning, the secretory activity of the lactogenic epithelium gradually decreases. Retained secretory products are removed by phagocytosis, although ruptured alveoli containing milk may be clinically manifested as galactoceles. Atrophy of glandular, ductal, and stromal elements results in a decrease in breast size. Withdrawal of the steroid hormones and growth factors of pregnancy and lactation results in apoptosis of the terminally differentiated secretory cells of the epithelial lumen. As previously noted, however, type 3 lobules persist.

Menopause

After menopause, the breast undergoes regression. Type 1 lobules predominate, as in the breasts of nulliparous women. Overall, involution of the ductal and glandular elements of the breast occurs, and the breast becomes predominantly fat and stroma. With aging, a progressive decrease in the fat content and supporting stroma results in breast shrinkage and loss of contour.

BREAST EXAMINATION

A careful history is the initial step in a breast examination. Regardless of the presenting complaint, baseline information regarding menstrual status and breast cancer risk factors should be obtained. The basic elements of a breast history are listed in Table 74.1. In premenopausal women, knowing the date of the last menstrual period and the regularity of the cycle is useful in evaluating breast nodularity, pain, and cysts. Postmenopausal women should be questioned about the use of hormone replacement therapy, given that many benign breast problems are uncommon after menopause in the absence of exogenous hormones. Specific information about the patient's presenting complaint is then elicited. A breast lump is most often the clinical problem that causes women to

seek treatment and remains the most common presentation of breast carcinoma. Today, many women present for a breast examination after an abnormality has been identified on a screening mammogram. Although the majority of these lesions are not clinically evident, a careful physical examination is an important part of the evaluation of a patient with an abnormal mammogram. Breast pain, a change in the size and shape of the breast, nipple discharge, and changes in the appearance of the skin are infrequent symptoms of carcinoma. The evaluation and management of these conditions are described in the section on clinical breast problems. For any breast complaint, the duration of the symptoms, their persistence over time, and their fluctuation with the menstrual cycle or relationship to exogenous estrogen should be ascertained.

Technique

A woman must be disrobed from the waist up for a complete breast examination. Although attention to modesty is appropriate and a gown or drape should be provided, inspection is an important part of the examination, and subtle abnormalities are best appreciated by comparing the appearance of both breasts. The breast examination should be performed with the patient in both the sitting and supine positions, and care should be taken at all times to be gentle. The steps of a breast examination are illustrated in Figure 74.4.

The breasts are initially inspected while the patient is in the sitting position with the arms relaxed. The size and shape of the breasts should be compared. If a discrepancy in size is noted, determine its chronicity. In many women, the breasts

FIGURE 74.4. Breast examination. **A:** The patient's ipsilateral arm is supported by the examiner to relax the pectoral muscle while the axillary nodes are examined. **B:** Bimanual examination of the breast in the upright position. **C:** Bimanual examination in the supine position with the arm raised over the head.

FIGURE 74.5. Breast asymmetry resulting from a benign phyllodes tumor. Skin changes are caused by pressure necrosis.

are not identical in size, and the finding of small discrepancies in size is rarely a sign of malignancy. Differences in breast size of recent onset or progressive in nature, however, may be caused by both benign and malignant tumors and require further evaluation (Fig. 74.5). Alterations in breast shape, in the absence of previous surgery, are of more concern. Superficially located tumors can cause bulges in the breast contour or retraction of the overlying skin. The skin retraction evident with superficial tumors may be caused by direct extension of tumor or fibrosis. Tumors deep within the substance of the breast that involve the fibrous septa (Cooper ligaments) can also cause retraction. Retraction is not itself a prognostic factor except when it is caused by the direct extension of tumor into the skin, and for this reason, it is not a part of the clinical staging of breast cancer.⁷ Although retraction is usually a sign of malignancy, benign lesions of the breast, such as granular cell tumors and fat necrosis, also cause retraction. Other benign causes of retraction include surgical biopsy and thrombophlebitis of the thoracoepigastric vein (Mondor disease).

The skin of the breast and the nipples should also be carefully inspected. Edema of the skin of the breast (*peau d'orange*), when present, is usually extensive and readily apparent. Localized edema is frequently most prominent in the lower half of the breast and periareolar region, and is most noticeable when the patient's arms are raised. Erythema is another sign of disease that is evident on inspection. It may be caused by cellulitis or abscess in the breast, but a diagnosis of inflammatory carcinoma should always be considered.

Examination of the nipples should include inspection for symmetry, retraction, and changes in the character of the skin. The new onset of nipple retraction should be regarded with a high index of suspicion, except when it occurs immediately after cessation of breast-feeding. Ulceration and eczematous changes of the nipple may be the first signs of Paget disease.

After inspection with the arms relaxed, ask the patient to raise her arms to allow a more complete inspection of the lower half of the breasts. A final inspection is made with the hands on the hips and the pectoral muscles contracted.

The regional nodes are then examined with the patient upright. Assess the size, character (soft, tender, firm), and number, and note whether the nodes are matted. The axillary nodes are most readily examined with the ipsilateral arm supported to relax the pectoral muscle (Fig. 74.4A). Bimanual examination of the breast is also carried out with the patient upright (Fig. 74.4B).

Complete the breast examination with the patient in the supine position and the ipsilateral arm raised above the head (Fig. 74.4C). Then systematically examine the breast tissue. Whether the examination is performed with a radial or a concentric circular search pattern is unimportant, provided that the entire breast is examined. The examination should extend superiorly to the clavicle, inferiorly to the lower rib cage, medially to the sternal border, and laterally to the midaxillary line.

One of the most difficult aspects of breast examination relates to the nodular, irregular texture of normal breasts in premenopausal women. Normal breasts tend to be most nodular in the upper outer quadrants, where the glandular tissue is concentrated; in the inframammary ridge area; and in the subareolar region. Generalized lumpiness is not a pathologic finding. Comparing the breasts is often helpful in determining whether a questionable area requires further evaluation. When the patient notices a mass that is not evident to the examiner, she should be asked to indicate the area of concern. If uncertainty remains regarding the significance of an area of nodular breast tissue in a premenopausal woman, a repeat examination at a different time during the menstrual cycle may clarify the issue. If a dominant mass is identified, measure it and record its location, mobility, and character in the medical record. The evaluation of a breast mass is discussed in detail in the section on clinical breast problems.

Screening Mammography

A screening mammogram consists of two views of the breast (craniocaudal and mediolateral oblique), which are obtained in asymptomatic women in an effort to detect cancer in a pre-clinical state, when the likelihood of cure is higher. It is important that screening not be confused with a diagnostic workup, which is performed to evaluate a woman with a clinical breast complaint and is discussed in the section on diagnostic imaging.

1 The ultimate measure of the effectiveness of a screening test is its effect on mortality. Eight randomized clinical trials, beginning with the Health Insurance Plan of New York study in 1963, have compared breast cancer mortality in women undergoing screening mammography at 1- to 2-year intervals with mortality in control populations. A 20% to 30% decrease in mortality has been demonstrated for screened women age 50 and older.⁸ The benefit of screening in women ages 40 to 49 has been controversial. Many of the trials were not designed to allow a separate analysis of women in this age group, and mortality benefits were often not apparent until after 8 years or more of follow-up. A meta-analysis of women ages 40 to 49 in the randomized trials, however, suggests a 29% mortality reduction with screening in this age group.⁹

The mortality reduction from screening is achieved by identifying abnormalities that cannot be detected on physical examination. These include microcalcifications and masses smaller than 1 cm in size, the usual clinical limit of detection. In addition to reducing breast cancer mortality, identifying smaller tumors increases the likelihood that a woman will be a candidate for breast-conserving surgery. In one study, only 10% of women with tumors 2 cm or less in size had contraindications to breast conservation, compared with 30% of women with tumors larger than 2 cm but less than 5 cm in size.¹⁰ Current screening recommendations are for annual mammography for women age 40 and older.

Screening mammography is a sensitive but nonspecific test, and only 20% to 30% of mammographically detected abnormalities that are examined further are found to be malignant. Biopsies for clinically occult, benign lesions represent the major induced cost of screening. The positive predictive value

FIGURE 74.6. Mammographic masses. **A:** Spiculated mass with calcifications. **B:** Lobulated mass with indistinct posterior margin. **C:** Well-circumscribed mass.

of a mammographic lesion varies with its appearance. For spiculated or stellate masses, the likelihood of malignancy is 75%; this falls to 20% for lobulated masses with slightly irregular margins and to 5% for well-circumscribed masses (Fig. 74.6). The classification of calcifications has proved to be even more difficult. Calcifications are analyzed based on their size, number, distribution, and morphology; those that are irregular in size and shape, particularly when they have a branching pattern suggestive of a ductal distribution, are most likely to be malignant (Fig. 74.7).

In an effort to standardize the reporting of mammographic abnormalities, the American College of Radiology has created a breast imaging reporting and data system (BI-RADS).¹¹ The BI-RADS classification is listed in Table 74.2. Category 3 lesions are those with a less than 2% probability of malignancy, and short-interval follow-up usually consists of repeated imaging studies at 6 months. Category 4 lesions range in risk from 2% to 50%, and a decision regarding biopsy is based on the appearance of the lesion and the patient's level of risk.

The BI-RADS also includes a category 0, which is used when analysis is incomplete and additional studies, such as magnification views or ultrasonography, are needed before a final BI-RADS classification can be assigned. In practice, the

TABLE 74.2 **CLASSIFICATION**

BI-RADS CLASSIFICATION OF MAMMOGRAPHIC ABNORMALITIES

CATEGORY	ASSESSMENT	RECOMMENDATION
1	Negative	Routine screening
2	Benign finding	Routine screening
3	Probably benign finding	Short-interval follow-up
4	Suspicious abnormality	Definite probability of malignancy; consider biopsy
5	Highly suggestive of malignancy	High probability of cancer; appropriate action should be taken

BI-RADS, breast imaging reporting and data system.

majority of abnormalities detected on screening mammography should undergo a diagnostic workup before biopsy. With additional views, the need for biopsy of benign lesions is often avoided, as illustrated in Figure 74.8, where what appears to be a mass lesion resolves with spot compression and magnification views. Sickles¹² reported that of 302 cases of calcifications felt to be equivocal (i.e., BI-RADS category 4) after a screening examination, 61% were shown to be benign on additional views. Even with lesions that are clearly malignant on a screening examination, additional views allow a better definition of the extent of the lesion for treatment planning.

**Biopsy Techniques for Lesions
Detected on Screening**

After a physical examination has confirmed that a mammographically detected abnormality is not clinically evident, a

histologic diagnosis can be obtained by needle localization and excision, or an image-guided core biopsy. For many years, needle localization with excision was the “gold standard” for the diagnosis of mammographic abnormalities. Recognition that the majority of mammographic abnormalities are benign, however, has resulted in the replacement of surgical biopsy with image-guided needle biopsy techniques.

Mass lesions can be sampled under ultrasonographic or stereotactic guidance; calcifications generally require stereotactic guidance. A comparison of the results of stereotactic core biopsy and surgical biopsy demonstrates concordance rates of 71% to 99%.^{13–15} Based on clinical experience, a number of circumstances in which a benign core biopsy should be followed by a surgical excision have been identified. These are listed in Table 74.3. The finding of atypical ductal hyperplasia on a core biopsy is associated with carcinoma in 18% to 50% of cases, even when large vacuum-assisted biopsy devices are used.^{15,24,25} The majority of these are intraductal carcinomas, but approximately one third are invasive

FIGURE 74.8. Workup of abnormal screening mammogram. **A:** Craniocaudal view showing an increased density with a slightly spiculated appearance (*arrow*). **B:** Spot magnification view of the density demonstrating normal breast tissue.

TABLE 74.3 INDICATIONS/CONTRAINDICATIONS**INDICATIONS FOR SURGICAL BIOPSY AFTER CORE BIOPSY**

- Atypical ductal hyperplasia
- Atypical lobular hyperplasia^{16–18}
- Radial scar
- Lobular carcinoma in situ^{16–19}
- Columnar cell hyperplasia with atypia
- Papillary lesions^{20–23}
- Lack of concordance between appearance of mammographic lesion and histologic diagnosis
- Nondiagnostic specimen (including absence of calcifications on specimen radiograph when biopsy is performed for calcifications)

lesions. Similarly, radial scar has been found to be associated with coexistent carcinoma in 20% of cases. Lesions suspected of being radial scars are best approached initially with needle localization and excision. Columnar cell lesions with atypia warrant surgical excision due to their frequent association with tubular carcinoma. Approximately 80% of patients with tubular carcinoma have associated columnar cell lesions with atypia.^{26,27}

Lack of concordance between the appearance of a mammographic abnormality and the histologic diagnosis obtained with core biopsy is an important indication for surgical biopsy. For example, the finding of a small amount of hyperplasia in a largely fatty specimen would not adequately explain a mass lesion identified on a mammogram. In addition, biopsies that reveal only fat, provide material insufficient for diagnosis, or lack calcifications on specimen radiography (if performed for

that indication) must be repeated. An assessment of the cause of an insufficient sample (i.e., superficial location of the lesion, poor targeting, breast too thin after compression) will aid in determining if a repeated core biopsy is appropriate or if surgical excision is needed.

- 2 For most mammographic abnormalities, core biopsy is a more cost-effective, less morbid diagnostic technique than needle localization and excision, and diagnosis by core biopsy increases the likelihood that local therapy will be completed with a single surgical procedure.^{28,29} When needle localization and excision is indicated, the localizing wire should be placed within 1 cm of the lesion, and the incision should be placed over the abnormality (Fig. 74.9). Incisions at the point of wire entry should be used only when the wire has a short course within the breast. Specimen radiography should be performed routinely to document removal of the target abnormality. The clinical approach to a patient with a mammographic abnormality is summarized in Algorithm 74.1.

CLINICAL BREAST PROBLEMS

Most breast complaints that cause a woman to seek medical attention are benign. The purpose of the evaluation of any breast problem is first to determine if it is caused by a benign or malignant condition. If the process is malignant, a prompt diagnosis with sufficient information to plan treatment is the goal. If the process is benign, reassurance and relief of troublesome symptoms are the goals. Clinical breast problems can be divided into the general categories of breast pain, nipple discharge, breast masses, and breast infections. Each is associated with different causes and a different risk for malignancy, and each is considered separately.

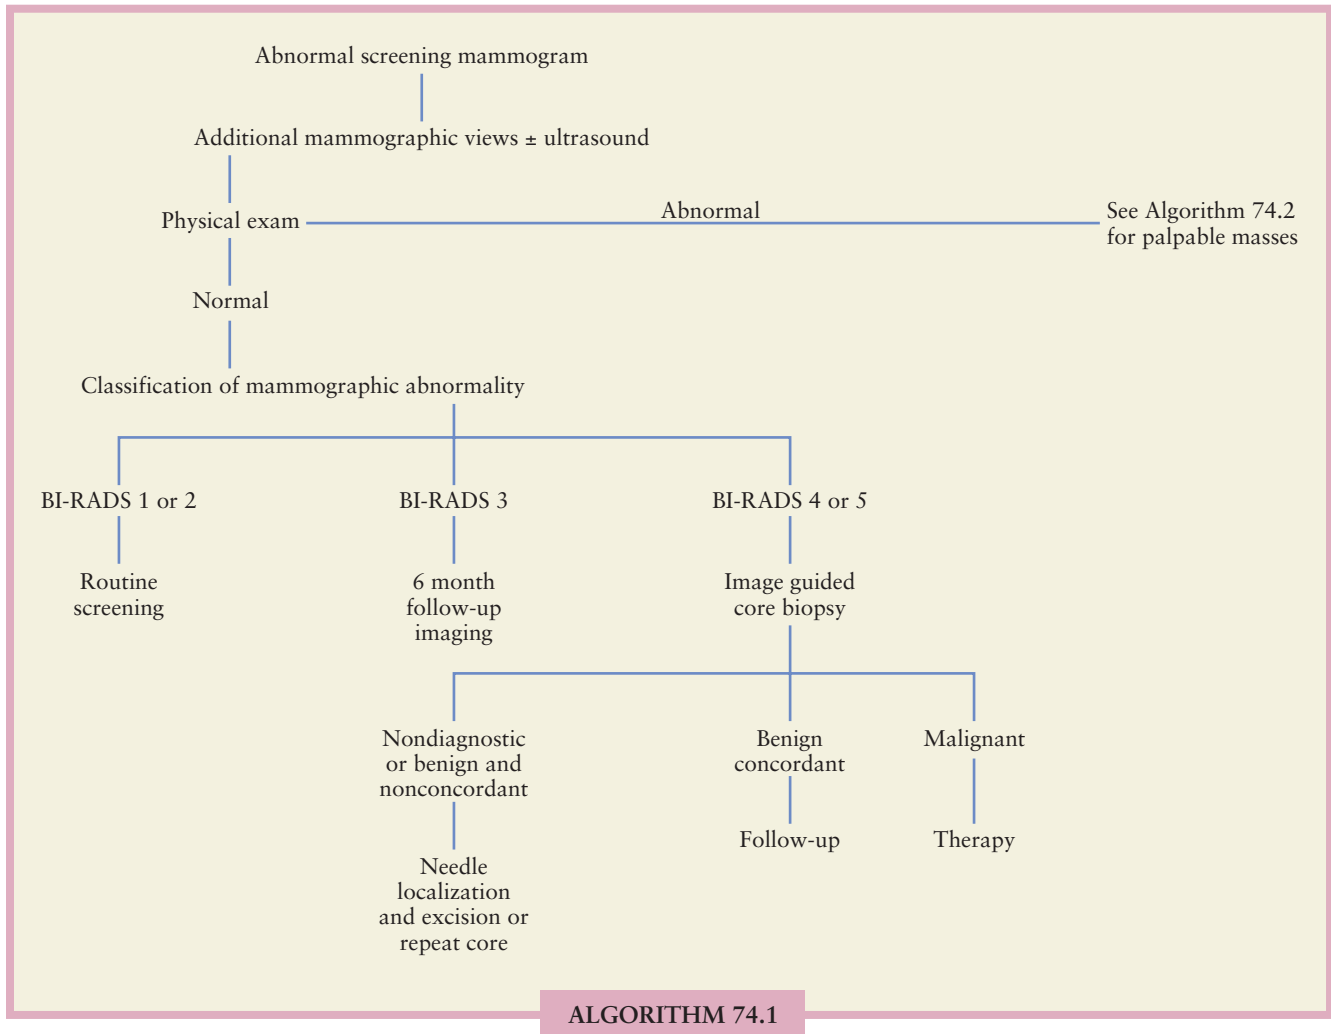

FIGURE 74.9. Incision placement for needle localization biopsy. **A:** The mammogram demonstrates that the lesion (arrow) is inferior to the point of wire entry. **B:** Incision placement inferior to wire entry to allow access to the lesion.

ALGORITHM 74.1. Diagnosis and management of mammographically detected breast lesions. A careful physical examination and a diagnostic imaging workup must be performed before a decision is made about the need for biopsy. *BI-RADS*, breast imaging reporting and data system.

Breast Pain

Breast pain is a common problem that is rarely a presenting sign of breast carcinoma. Breast pain may originate from the breast itself or may be referred from extramammary structures, such as the ribs, the vertebrae, or occasionally the teeth. Clinically, breast pain can be divided into two categories: cyclic and noncyclic. Cyclic breast pain waxes and wanes with the menstrual cycle, is frequently bilateral, and often involves the upper outer quadrants of the breasts with radiation to the axillae or down the arms. It tends to be most severe immediately before the menses, but may persist throughout the month. In contrast, noncyclic pain occurs in postmenopausal women or, in premenopausal women, bears no relationship to the menstrual cycle.

No specific hormonal abnormalities or histologic correlates have been identified in women with breast pain, but the problem is clearly hormonally related because it affects premenopausal women much more frequently than their postmenopausal counterparts. Breast pain is often precipitated by hormonal change, and a history of menstrual irregularity or a new medication should be sought. In the evaluation, it is important to ascertain whether fear of an underlying cancer or

the need for pain relief is the patient's primary concern. In almost all cases, fear of cancer predominates. A careful physical examination should be performed to exclude a specific cause of the pain, particularly for focal, noncyclic mastalgia, which is occasionally secondary to the presence of a fibroadenoma or cyst and may be relieved by treatment of the underlying lesion. In women age 35 and older, a mammogram is usually part of the evaluation of breast pain unless one has been obtained within the preceding year. In the vast majority of women with breast pain, examination and mammography demonstrate no evidence of breast disease. In these cases, reassurance that a malignancy is not the cause of the pain and a discussion of the normal physiology of the breast are usually all that is necessary. In the patient with persistent, localized pain, physical examination should be accompanied by imaging studies, including ultrasound, to exclude the presence of carcinoma.

Approximately 5% of patients have disabling breast pain requiring further treatment. Several agents have been tested in randomized controlled trials; these include danazol (an anti-gonadotropin),³⁰ bromocriptine (a dopaminergic agonist),³¹ and tamoxifen (a selective estrogen receptor [ER] modulator).³² Danazol, which appears to be more effective than bromocriptine, has a response rate of approximately 50% for

FIGURE 74.10. Mondor disease. Thrombophlebitis of the thoracoepigastric vein causes retraction of the lateral portion of the breast, which crosses to the midline at the inferior areolar margin and is accompanied by a palpable cord.

cyclic pain at doses of 100 to 400 mg, but is recommended only for severe, activity-limiting pain because of its side effects, which include menstrual irregularity, acne, weight gain, and hirsutism.³³ In addition, women starting therapy with danazol should be advised to use barrier contraception because of potential teratogenicity and possible interference with oral contraceptives. Tamoxifen appears to be effective at doses of 10 mg daily and has been used for 3- to 6-month intervals for the treatment of breast pain, but long-term use is not recommended because of its serious adverse effects (see later). Other agents, such as vitamins E and B₆, diuretics, and avoidance of caffeine have failed to demonstrate a reduction in symptoms in controlled clinical trials.^{34–36} Evening primrose oil, which contains the long-chain fatty acid γ -linolenic acid, has also been proposed as therapy for cyclic breast pain, but clear evidence of its efficacy is lacking. Surgery should be avoided, even for apparently localized pain, because it rarely results in long-term pain relief.

Mondor disease, or thrombophlebitis of the lateral thoracic or superior thoracoepigastric vein, is an uncommon cause of breast pain that is readily identified clinically by the presence of a tender, subcutaneous cord in the lateral aspect of the breast. Skin retraction may be associated (Fig. 74.10), which raises concern about the presence of carcinoma. Mondor disease may develop secondary to trauma, surgical procedures on the breast, or breast irradiation. In approximately 50% of cases, no predisposing condition can be identified. Mondor disease occurs occasionally in women with a nonpalpable breast cancer,³⁷ and for this reason, a mammogram should be obtained in women age 35 and older who present with the condition. Mondor disease resolves spontaneously and requires no specific therapy, although anti-inflammatory agents may be used for pain relief.

Nipple Discharge

Evaluation. Nipple discharge is a common complaint, particularly in premenopausal women, and has a benign cause in approximately 95% of women who present with it. The initial

step in the evaluation of nipple discharge is to determine whether it is physiologic or pathologic. Discharges are considered pathologic if they are spontaneous and localized to one duct; they may be bloody or serous and are almost always unilateral. In one study, 32% of women over the age of 60 who presented with pathologic nipple discharge and no mass had carcinoma, compared with 7% of women under age 60 with the same presentation.³⁸ In contrast, physiologic discharges occur only with nipple compression, frequently originate from multiple ducts, and are often bilateral. If the remainder of the breast evaluation is normal, patients with physiologic discharge should be advised to stop squeezing their nipples and be assured that no further therapy is needed.

The clinical evaluation of a pathologic discharge should include testing the fluid for occult blood and identifying the quadrant of the breast from which the discharge originates. Although 70% to 85% of the discharges associated with carcinoma contain blood,³⁹ a nonbloody discharge that meets the other criteria of a pathologic discharge is an indication for further evaluation. Cytology is not usually useful in the evaluation of nipple discharge because the absence of malignant cells does not reliably exclude carcinoma, and false-positive cytologic findings are not rare.⁴⁰ Mammography and ultrasonography should be performed and may identify nonpalpable masses, calcifications, or dilated ducts. The presence of imaging abnormalities in women with a pathologic nipple discharge increases the likelihood of malignancy⁴¹ and biopsy of the abnormality should be performed. The role of galactography in the management of nipple discharge is controversial. Although ductal lesions are visualized in many women (Fig. 74.11), biopsy is still required to determine whether they are benign or malignant, and a normal galactogram in a woman with a pathologic discharge does not reliably exclude the presence of significant ductal disease.^{40,42} Galactography or ductoscopy (mammary endoscopy),⁴³ however, may be useful in identifying lesions in the periphery of the breast that would not be removed with a standard terminal duct excision, and in minimizing the portion of the ductal system that is removed in women of childbearing age.

Galactorrhea, defined as the nonpuerperal discharge of milky fluid from both nipples, is not a sign of primary breast pathology. It should prompt a workup to exclude an underlying endocrine disorder, particularly a variety of amenorrhea syndromes that result in hyperprolactinemia. In addition, it may be secondary to hypothyroidism, pituitary adenoma, or chest trauma (including thoracotomy). A variety of medications, including oral contraceptives, phenothiazines, tricyclic antidepressants, metoclopramide, and reserpine, also cause galactorrhea. Persistent galactorrhea in a patient not taking any of these medications should be evaluated with measurement of the prolactin level. A persistently elevated prolactin level should prompt a search for a pituitary adenoma, but if there is no evidence of an endocrine abnormality, these women may be followed without intervention.

3 Etiology. The most common cause of pathologic discharge identified in surgical specimens is a solitary papilloma (about 60% of cases); these lesions are most common in the major subareolar ducts. They consist of an epithelial layer covering a fibrovascular stroma. Peripheral papillomas are a distinctly different clinical entity in which multiple papillomas develop in the peripheral ducts of the breast. These lesions are less likely to produce nipple discharge and tend to present as a palpable or image-detected mass.⁴⁴ Duct hyperplasia, typical or atypical, is found in 15% to 20% of women undergoing duct excision for spontaneous nipple discharge, whereas ductal carcinoma in situ is found in 5% to 20%.^{39,41} Invasive carcinoma presenting as discharge alone is rare. Ductal ectasia may also cause nipple discharge, which is classically thick and opaque, and varies in color from pale yellow to blue-green. It

FIGURE 74.11. Ductogram. A large defect (arrows) represents an intraductal papilloma.

may be accompanied by periductal mastitis, causing nipple inversion, and mimic carcinoma. The discharge of ductal ectasia is sometimes mistaken for an infectious process, but the ducts are usually sterile.⁴⁵

Management. When a pathologic discharge has been identified, an attempt should be made to localize the source of the discharge within the ductal tree by galactography, or by ductoscopy. If the intraductal lesion is centrally located, terminal duct excision, also called *microdochectomy*, is the appropriate management. If the lesion is peripheral, it is necessary to localize it for excision, either by wire localization of the abnormal area on galactogram, or by ductoscopy immediately preceding the surgical excision. In a woman with clearly pathologic nipple discharge, it is reasonable to proceed with terminal duct excision even if radiologic investigations (including galactography) are normal.^{40,42} Exceptions to this rule include women with a single, nonreproducible episode of discharge with normal imaging evaluation, and women with bloody nipple discharge during pregnancy.

Terminal duct excision is carried out through a circumareolar incision that includes a quarter to a third of the circumference of the areola. Duct removal should begin on the dermal surface of the nipple, as ductal disease often occurs in the proximal duct. The dilated duct is visualized after the subareolar space has been entered and excised to a depth of 2 to 3 cm in the breast parenchyma. Identification of the diseased duct can be aided by inserting a lacrimal probe into the discharging ductal orifice, or the instillation of blue dye. If ductoscopy is performed before the duct excision, the outer cannula of the endoscope can be left in place to guide resection of the appropriate segment of the duct. Patients should be warned that some nipple sensation may be lost after the procedure, in addition to the ability to breast-feed.

Breast Masses

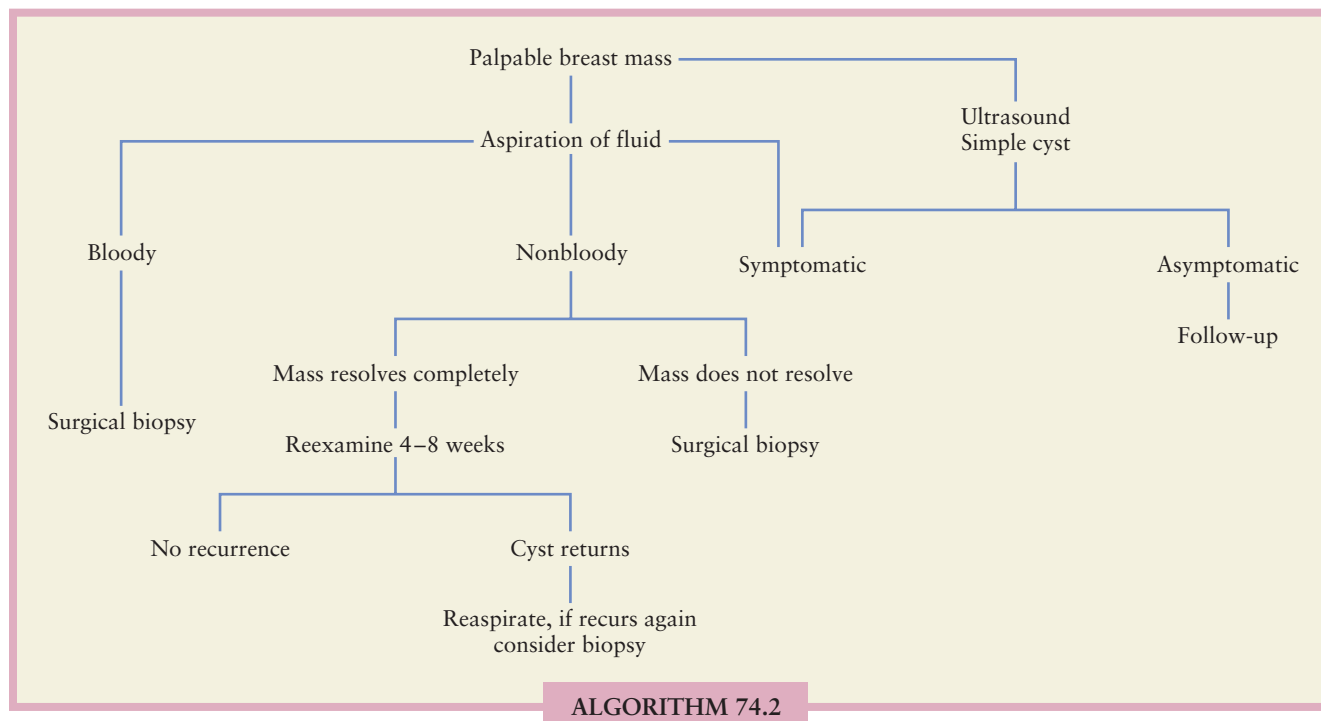

Definition. The first step in the evaluation of a woman with a complaint of a breast mass is to verify that a dominant mass is actually present. Dominant masses may be cystic or solid and are characterized by their persistence throughout the menstrual cycle. They may be discrete or poorly defined, but they differ in character from the surrounding breast tissue and the corresponding area in the contralateral breast. Often, what the patient perceives as a breast mass is actually a normal variant

of breast tissue. In premenopausal women, the normal glandular tissue of the breast is nodular, and patients often confuse such nodular glandular tissue with a dominant breast mass. Nodularity, particularly when it waxes and wanes during the menstrual cycle, is a physiologic process and not a predictor of breast disease. Morrow et al.⁴⁶ reviewed 605 women younger than 40 years of age who were referred for evaluation of a breast mass. Only 36% of the 484 masses detected by patient self-examination and 29% of the 121 masses detected by a primary care provider were confirmed surgically. The differential diagnosis of a palpable breast mass includes macrocyst, fibroadenoma, prominent areas of fibrocystic change, fat necrosis, and carcinoma.

Cysts. Cysts are a common cause of dominant breast masses, with a peak incidence in women in their 40s and perimenopausal years. Cysts are thought to result from cystic lobular involution; acini within the lobule distend to form microcysts, which in turn give rise to macrocysts. Clinically evident macrocysts are estimated to develop in 7% of Western women.

Cysts are usually well demarcated from the surrounding breast tissue, mobile, and firm. It is often difficult to distinguish a cystic from a solid lesion on physical examination, although cysts may fluctuate with the menstrual cycle, whereas solid lesions do not. Cystic lesions in postmenopausal women who are not on hormone replacement therapy are uncommon, and they should be regarded with a higher degree of suspicion than those found in premenopausal women because they may be secondary to ductal obstruction by a malignant lesion.

4 The initial step in the evaluation of a possible cyst is aspiration. If fluid is obtained that is not grossly bloody and the mass resolves completely, no further therapy other than a follow-up examination is needed. However, if the cystic fluid is bloody, the palpable abnormality does not resolve completely, or the same cyst recurs multiple times in a short time period, a biopsy to exclude the presence of a malignant lesion in the cyst wall is required. Cytologic examination of cyst fluid is of little value because intracystic carcinoma is rare and malignant cells are identified in fewer than 1% of cases.⁴⁷ The presence of atypical cells, an indication for surgical biopsy, is not uncommon when cyst fluid is examined, and it may pose a dilemma when a patient's cyst has resolved with aspiration, and the examination and mammographic findings are now normal.

ALGORITHM 74.2. Diagnosis and management of cystic lesions. Bloody fluid on aspiration, failure of the mass to resolve completely, and prompt refilling of the same cyst are indications for surgical biopsy.

Many patients present to the surgeon with a palpable mass and an ultrasonographic examination demonstrating that the mass is a simple cyst. If the cyst is symptomatic or alarming to the patient, it can be aspirated. Otherwise, because the diagnosis has been made, it can be left alone. Nonpalpable lesions that are proved to be simple cysts by ultrasonography do not require aspiration. The management of cystic lesions is summarized in Algorithm 74.2. A dominant breast mass should not be dismissed as a cyst unless the diagnosis is confirmed by ultrasonography or aspiration of fluid.

Solid Masses

Fibroadenomas. Fibroadenomas present most frequently in patients between the ages of 20 and 50 years. Their characteristic clinical presentation is that of a well-defined palpable mass that is rubbery in texture and mobile. Fibroadenomas present as multiple lesions in 10% to 15% of cases. Although they have a characteristic clinical appearance, a clinical diagnosis of fibroadenoma is accurate in only one half to two thirds of cases.⁴⁸ In women younger than age 20, however, fibroadenomas account for 75% of breast biopsies.

Fibroadenomas are thought to be the result of a minor aberration in the normal process of lobular development. Hormonal factors appear to be important in their growth, as evidenced by the clinical observation of the involution of fibroadenomas after menopause and their dramatic increase in size during pregnancy. In postmenopausal women receiving estrogen alone, fibroadenomas may increase in size relative to the surrounding breast parenchyma.

Sonographic criteria for the diagnosis of fibroadenoma include a round or oval, well-circumscribed, solid mass with homogeneous, low-level internal echoes and intermediate acoustic attenuation. As many as 30% of fibroadenomas, however, lack these “classic” features.

In rare circumstances, fibroadenomas have been associated with carcinoma. More than 160 cases of associated cancers

have been reported in the literature, including ductal carcinoma in situ, and infiltrating lobular and ductal carcinomas. Historically, it has been widely accepted that fibroadenomas do not confer an increased breast cancer risk. However, four population-based retrospective studies have shown a small (relative risk of 1.3 to 1.9) but significant increased risk for breast cancer development that persists over time.^{49–52} This slight increase in risk should have no impact on the clinical management of fibroadenomas. Although fibroadenomas can be suspected on the basis of their characteristic clinical presentation, a final diagnosis cannot be made without histologic or cytologic confirmation.

Fibrocystic Disease. *Fibrocystic disease* is a common term that is used to describe a variety of benign breast disorders. It is not a clinically meaningful term because it encompasses a heterogeneous group of processes, some pathologic and some physiologic, with widely varying cancer risks. The cancer risks associated with benign breast disease are discussed in the section on breast cancer risk factors. The term *fibrocystic change* is not a synonym for lumpy breasts and, if used at all, it should be reserved for women in whom a breast biopsy has demonstrated one of the histologic components of fibrocystic change. Frequently, when a breast biopsy is performed for vague areas of nodularity that lack mammographic or ultrasonographic correlates, a fibrocystic process is the diagnosis.

Fat Necrosis. Fat necrosis in the breast may occur secondary to trauma, breast surgery, infection, or radiation therapy, although in approximately 50% of cases, no antecedent cause can be identified. Fat necrosis occurs most commonly in women with pendulous breasts and those who are overweight. It is clinically significant in that on both physical examination and mammography, it may be indistinguishable from carcinoma. The lesions of fat necrosis are typically firm, painless, and poorly defined. Because fat necrosis usually

FIGURE 74.12. Oil cysts. The calcified rims of these cysts in a patient with a history of trauma are diagnostic.

occurs in the superficial breast tissue, it may be accompanied by skin thickening, dimpling, or retraction. The mammographic findings of fat necrosis include spiculated masses, microcalcifications, and architectural distortion. Only when the characteristic oil cyst, a circumscribed mass of mixed soft tissue density and fat with a rim that is often calcified, is present can an unequivocal diagnosis of fat necrosis be made radiographically (Fig. 74.12). In the absence of this finding or a clear history of trauma, biopsy is required to exclude the presence of malignancy.

Diagnostic Imaging

Mammography and Ultrasonography. When a clinical abnormality has been identified in a woman over age 40, a diagnostic mammogram should be obtained before a histologic diagnosis is attempted. Imaging studies are used to define the extent of a potential malignancy and to identify nonpalpable masses or associated calcifications elsewhere in the ipsilateral or contralateral breast that might influence definitive therapy. The decision to perform a biopsy, however, is based on the clinical determination that a dominant mass is present, and nonvisualization of a mass on imaging studies should not dissuade the surgeon from performing a breast biopsy. In two reports, between 10% and 22% of patients with palpable breast cancer had tumors that were not visible by mammography.^{53,54} Obtaining a diagnostic rather than a screening mammogram ensures that a marker will be placed on the area of palpable concern, so that the clinical and radiographic findings can be correlated. Identifying the site of a lesion also ensures that lesions at the periphery of the breast will be included on the film, which helps to eliminate one cause of false-negative mammograms. A diagnostic mammogram also includes magnification views of the lesion, which are useful in determining the extent of any associated calcifications.

The routine use of ultrasonography for the evaluation of solid palpable masses remains controversial. Studies of high-resolution ultrasonography have demonstrated that the tech-

nique is more accurate and sensitive, and has a better negative predictive value than mammography alone.⁵⁵ If follow-up of a clinically benign lesion is being considered, ultrasonography is a useful adjunct to mammography, as discussed in the section on the clinical approach to the patient with a solid breast mass. In the patient with a clinically suspect mass who will undergo biopsy regardless of the results of imaging studies, ultrasonography provides a more accurate estimate of lesion size than mammography,⁵⁶ and it may also identify satellite lesions not identified on mammography. Ultrasonography is also useful in the woman with a palpable mass that is not clearly delineated on mammography; in such cases, it may help to define the extent of the lesion more completely than physical examination alone.

In women under age 40 presenting with a clinically unworrisome breast mass, the rationale for mammographic imaging is less compelling because carcinoma is uncommon and the density of the breasts often obscures mass lesions. Directed ultrasonography allows the presence of a true mass lesion to be confirmed when the significance of a physical finding is clinically uncertain.⁴⁶ The presence of benign characteristics on ultrasonography also supports the use of a follow-up approach. In younger women with clinically suspect masses, mammography should be performed.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) of the breast is increasingly being used for clinical breast imaging. Initially it was hoped that MRI would reduce the number of biopsies done for benign breast lesions. However, in a prospective study of 821 breast abnormalities identified mammographically (404 malignant), the sensitivity and specificity of MRI for the diagnosis of carcinoma were 88% and 68%, respectively.⁵⁷ These findings indicate that a normal MRI does not obviate the need for biopsy of a lesion that has suspicious clinical or mammographic features.⁵⁷ There is great interest in the use of MRI in women with known breast cancer to improve selection for breast-conserving therapy (BCT). In a meta-analysis of 19 studies involving 2,763 breast cancer patients, MRI identified additional disease in 16% of patients, resulting in a mastectomy or wider surgical excision that would not have been done otherwise.⁵⁸ It is not clear that these more extensive procedures are beneficial to patients. In one retrospective study, local recurrence rates did not differ between women selected for BCT with and without MRI.⁵⁹ A decrease in the need to convert from BCT to mastectomy, or a greater likelihood of obtaining negative margins with a single excision have not been demonstrated in patients selected for BCT with MRI,⁶⁰ so the ultimate role of this technology in the patient with cancer remains to be determined.

Other clinical applications of MRI are to detect an implant rupture and to look for a primary breast tumor in patients presenting with axillary adenopathy caused by metastatic tumor from an unknown primary site (see section on occult primary tumor presenting with nodal metastases). MRI also has a role in assessing the response of a tumor to preoperative chemotherapy is also under study. The role of screening MRI in women at very high risk of breast cancer development is discussed in the section on management of the high-risk woman.

Biopsy Techniques for Solid Breast Masses. A variety of biopsy techniques are available to obtain a pathologic diagnosis of clinically evident breast masses. Each has advantages and disadvantages, and no single technique is applicable to all clinical circumstances.

Fine-needle Aspiration Biopsy. Fine-needle aspiration (FNA) cytology has a very high diagnostic accuracy rate in the hands of experienced clinicians and cytopathologists. In a review of 31,340 procedures,⁶¹ its sensitivity ranged from 65% to 98%.

TABLE 74.4 **TREATMENT**

MANAGEMENT OF BREAST MASSES BASED ON FINE-NEEDLE ASPIRATION (FNA) DIAGNOSIS

FNA DIAGNOSIS	TREATMENT
Malignant	Definitive therapy
Suspicious	Surgical or core needle biopsy
Atypia	Surgical biopsy
Benign	Possible observation ^a
Nondiagnostic	Repeated FNA or surgical biopsy

^aSee discussion in text on clinical approach to the patient with a solid breast mass.

In most series, false-positive rates are less than 1%, false-negative rates are below 10%, and the incidence of insufficient specimens ranges from 4% to 13%. Small tumor size, fibrotic tumors, and certain histologic tumor types, such as infiltrating lobular, tubular, and cribriform carcinoma, have been associated with a higher likelihood of false-negative results. Most false-negative results are the consequence of sampling errors rather than misinterpretation by the cytopathologist.

The advantages of FNA include its simplicity and quickness, low cost, low morbidity, and availability as an office procedure. Because an unequivocal diagnosis of malignancy by FNA is reliable, treatment options can be discussed with the patient and definitive surgery can be performed without the need for a surgical biopsy. The management of breast lesions on the basis of FNA results is summarized in Table 74.4.

Core Needle Biopsy. Core needle biopsy is another office diagnostic technique that is rapid, inexpensive, and relatively painless. A core needle biopsy differs from FNA in that a core of tissue is obtained for histologic examination, so that a more detailed characterization of the lesion is possible and the ade-

quacy of the specimen can be evaluated at the time of the biopsy. In addition, the material can be evaluated by any surgical pathologist. A core biopsy specimen allows the determination of ER and HER2 status at the time of diagnosis. False-negative results occur when the needle is deflected into the surrounding fat by a hard tumor mass. In practice, the selection of the type of needle biopsy (FNA or core) often depends on the availability of a cytopathologist and the surgeon’s level of comfort with a cytologic diagnosis of malignancy without further histologic detail, although core biopsy is preferred in patients who will receive neoadjuvant therapy. The difference between an FNA specimen and a core needle specimen is illustrated in Figure 74.13.

Excisional Biopsy. Excisional biopsy is the complete removal of a breast mass. It is definitive therapy for a benign breast mass and may also serve as a therapeutic lumpectomy if the specimen includes a margin of normal breast tissue around a malignant tumor. The adequacy of an excision cannot be assessed unless the margins of the specimen are inked. The use of orienting sutures in two margins of the specimen makes it possible to identify which margin contains tumor should the excision be incomplete; as a result, less normal breast tissue has to be removed in a repeated excision. In this era of breast-conserving surgery, orientation and inking of excisional breast biopsy specimens should be routine practice.

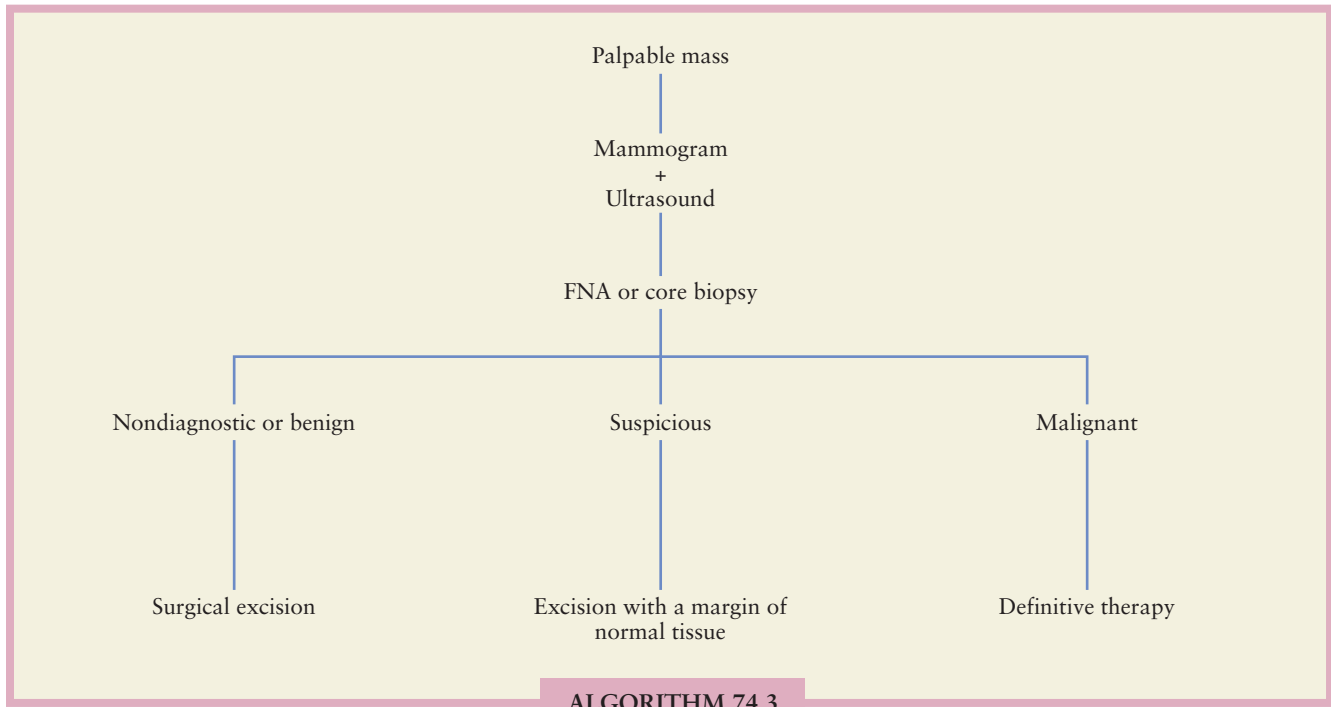

However, diagnosis by needle biopsy techniques is reliable, more cost-effective than surgical biopsy, and avoids placement of an incision on the breast before definitive local therapy. For the vast majority of breast masses, needle biopsy is the preferred diagnostic technique.

Incisional Biopsy. Incisional biopsy is a diagnostic procedure reserved for masses that are too large to be completely excised. Today, the indications for incisional biopsy are few, because FNA or core needle biopsy can be used to make a diagnosis of breast cancer with less morbidity and at lower cost.

Clinical Approach to the Patient with a Solid Breast Mass. The accuracy of physical examination alone to detect carcinoma is limited because the clinical characteristics of benign and malignant masses are not absolute, and a clinical diagnosis is

FIGURE 74.13. Comparison of core needle biopsy specimen (A) and fine-needle aspiration specimen (B). Only the core specimen can demonstrate the architectural detail.

**ALGORITHM 74.3**

ALGORITHM 74.3. Diagnosis and management of the patient with a clinically indeterminate or suspect solid breast mass. In this circumstance, imaging studies are insufficient to exclude malignancy, and tissue sampling is required.

correct in only 60% to 85% of cases.^{62,63} The difficulty of distinguishing benign from malignant lesions is greatest in young women, and the use of other studies to confirm the clinical diagnosis of a benign breast mass is essential before the patient is returned to routine follow-up.

The extent of the workup necessary to exclude the presence of carcinoma varies with the degree of suspicion and the age of the patient. In the patient with a clinically suspect mass, regardless of age, diagnostic mammography and ultrasonography should be performed before a histologic diagnosis is sought. A needle biopsy (either aspiration cytology or core biopsy) is the preferred initial method of making a diagnosis, for the reasons discussed in the preceding section on biopsy technique. If a diagnosis of malignancy is obtained, treatment options are discussed with the patient. If a diagnosis of cancer is not obtained, excisional biopsy is undertaken because of the known false-negative rates of both FNA and core biopsy. This approach is summarized in Algorithm 74.3.

In the woman with a clinically benign mass, management varies somewhat with age (Algorithm 74.4). In women under age 40, the first step is to determine if the patient wants the mass to be excised, regardless of the likelihood of malignancy. If so, imaging studies are not indicated because of the low risk for carcinoma in this age group. For the patient who desires follow-up, ultrasonography and FNA or core biopsy should be performed. If both confirm that the lesion has benign features, clinical follow-up can be undertaken, with regular monitoring of the lesion for a period of 1 to 2 years to confirm that carcinoma is not present. The combination of clinical examination, FNA, and ultrasonography provides an accurate differentiation between benign and malignant lesions in 95% of cases.⁶⁴ For this reason, in addition to the low risk for malignancy in this age group, follow-up is a safe approach.

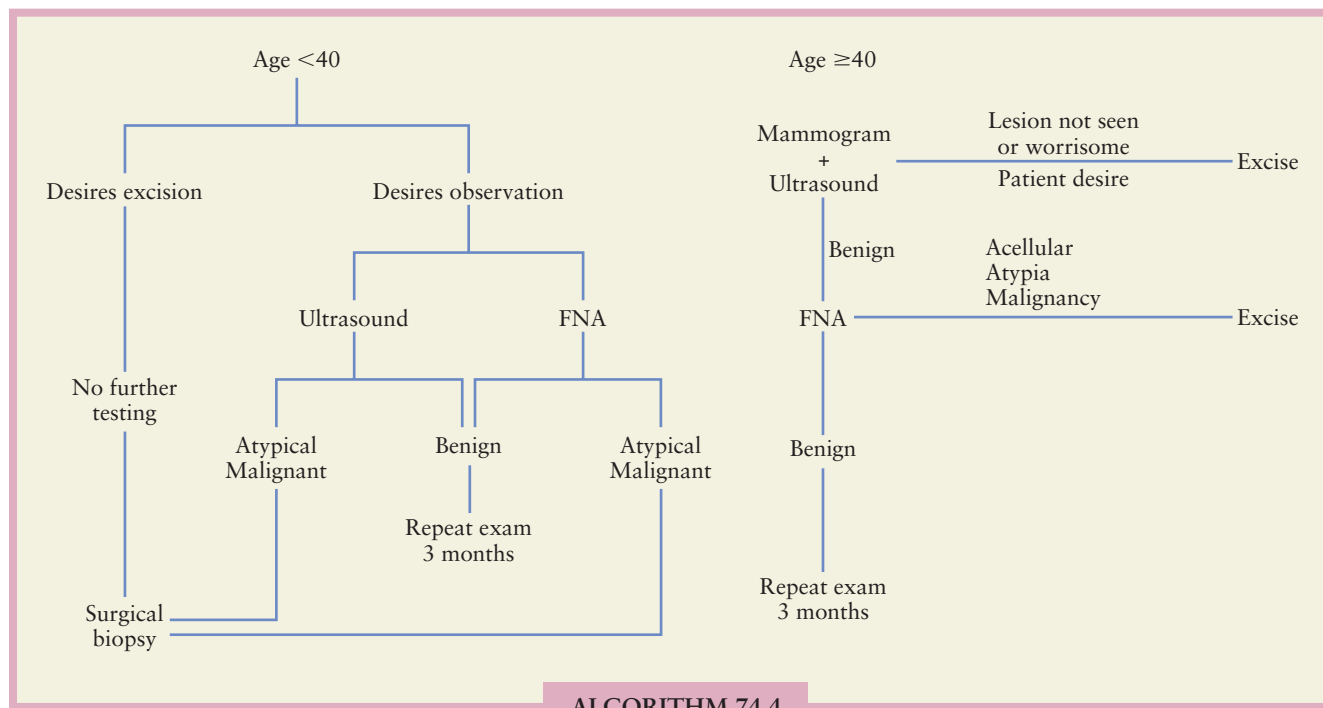

In patients over age 40, mammography and ultrasonography should be obtained before a decision about the need for

excision or follow-up is made. If follow-up is chosen, needle biopsy is also performed. If the mass is visualized on mammography and appears benign, and if the needle biopsy is benign, the risk for carcinoma ranges from 0.6% to 3.4%.^{65,66} It must be emphasized that if any elements of the “triple test” cannot be evaluated (i.e., lesion not visualized on imaging studies, aspirate contains only blood and fat), these statistics do not apply. A follow-up approach to new breast lesions in women older than age 40 should be undertaken only by clinicians with experience in the management of breast disease, and patients must be advised of the small, but real, possibility of a delay in the diagnosis of breast carcinoma.

Breast Infections

Breast infections can be classified as lactating or nonlactating. Lactating infections are usually caused by *Staphylococcus aureus*, and are most common during the first 4 to 6 weeks of breast-feeding or during weaning. They are caused by the proliferation of bacteria in poorly drained breast segments, and present as cellulitis with fever, pain, redness, and swelling. Antibiotics are the first line of treatment, and breast-feeding should be continued to facilitate drainage of the engorged segment. Tetracycline, chloramphenicol, and ciprofloxacin should be avoided because they enter breast milk. If the infection fails to resolve, an abscess should be considered. When the breast skin is intact, repeated aspiration of the abscess combined with antibiotics is the preferred treatment.⁶⁷ When the skin is thinned, a small incision will facilitate drainage.

In nonlactating women, a syndrome characterized by periareolar inflammation, sometimes associated with a purulent nipple discharge, which affects premenopausal women, is the most common form of breast infection. Periareolar abscess and mammary duct fistulas may develop secondary to this

ALGORITHM 74.4. Diagnosis and management of clinically benign breast masses. The use of imaging studies varies according to age because carcinoma is infrequent in women under age 40.

condition, and infection can be troublingly recurrent. Recurrent periareolar abscess is associated with smoking,⁶⁸ apparently by promoting squamous metaplasia of the duct lining.⁶⁹ Antibiotics that provide coverage for aerobic and anaerobic bacteria should be used in patients with periareolar inflammation without abscess formation. Abscesses can be treated with aspiration. For patients with recurrent episodes of infection, terminal duct excision is indicated.

Peripheral breast abscesses, which are less common than periareolar infections, should be treated with aspiration or incision and drainage. In any patient with a breast infection, particularly in older women, the possibility of an underlying malignancy should be considered. A biopsy should be performed on any apparent “infection” that fails to respond to appropriate antibiotics and drainage to exclude the presence of an underlying carcinoma.

RISK FACTORS FOR BREAST CANCER

Breast cancer is the most common cancer in American women, the second most common cause of cancer death, and a major cause of cancer death in most industrialized nations. Approximately 180,000 cases of breast cancer and 41,000 breast cancer deaths occur annually in American women.⁷⁰ Many factors that increase the risk for the development of breast cancer have been identified, and have become clinically important since the demonstration that chemoprevention can protect high-risk women from breast cancer (see section on management of the high-risk woman). Risk can be described as the absolute risk for the development of breast cancer, either over the lifetime (usually to age 90) or within a given time interval (e.g., 2.5% during the next 5 years). Risk may also be expressed as a relative risk (RR), a comparison of the incidence of disease in a population having a particular risk factor with the

incidence in a population lacking that risk factor. Understanding the clinical implications of RR requires knowledge of the absolute risk of breast cancer in the index population and, although it is a useful measure for research purposes, it is not particularly useful for the discussion of risk clinically. Risk information is best provided to patients as absolute risk within a given time period.

Age

The most common breast cancer risk factor is age. Half of a woman's lifetime risk for breast cancer development occurs after age 65. Between the ages of 35 and 55, the risk for breast cancer development is only 2.5%, and the risk for breast cancer death is only about one third of that.⁷¹ The incidence of breast cancer across age groups has been fairly stable, although an increase in the number of young women in the population has resulted in an increase in the number of cases in this group, without a change in incidence rate. Breast cancer at a young age is more common in black women than in white women. At age 40, the incidence curves cross, and the disease becomes more common in white women.

Family History

- 6 There are two distinct types of risk associated with a family history of breast carcinoma. Approximately 20% to 30% of women with breast cancer have a family history of the disease, but only 5% to 10% have an inherited mutation in a breast cancer susceptibility gene.^{72,73} Distinguishing between familial and true hereditary breast cancer is important because the associated level of risk varies widely.

The majority of cases of genetic breast cancer are caused by mutations of *BRCA1* and *BRCA2*. Mutations of either of

TABLE 74.5

RESULTS

ESTIMATED LIFETIME CANCER RISKS FOR *BRCA1* AND *BRCA2* MUTATIONS (TO AGE 70)

■ TYPE OF CANCER	■ GENERAL POPULATION (%)	■ <i>BRCA1</i> CARRIER (%)	■ <i>BRCA2</i> CARRIER (%)
Breast cancer	8.0	40–85	40–85
Contralateral breast cancer	0.5–1/y	40–65	40–65
Male breast cancer	0.1	1–5	5–10
Ovarian cancer	1.4	30–45	10–20

Modified from Isaacs C, Peshkin BN, Lerman C. Evaluation and management of women with a strong family history of breast cancer. In: Harris JR, Lippman ME, Morrow M, et al., eds. *Diseases of the Breast*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:316.

these genes carry a lifetime risk for breast cancer development of 37% to 85%,^{74,75} a high risk of contralateral breast cancer, and an increased risk for ovarian cancer. Although the risk for ovarian cancer is elevated with mutations of both *BRCA1* and *BRCA2*, it is greater in carriers of the *BRCA1* mutation. In *BRCA2* families, the risk for male breast cancer, prostate cancer, and pancreatic cancer is increased.^{76,77} These mutations can be inherited from both maternal and paternal relatives, and are summarized in Table 74.5. The carrier frequency of these mutations varies with the population under study. The frequency of *BRCA1* mutations is between 1 in 500 and 1 in 800, and the frequency of *BRCA2* mutations is lower in the general population. In persons of Ashkenazi Jewish descent, however, two specific mutations of *BRCA1* (185delAG and 5382insC) and one *BRCA2* mutation (6174delT) occur with a background frequency of 2.3%.⁷⁴ These are known as *founder mutations*, thought to arise from

common ancestry, and have been identified in other ethnic populations in Iceland, France, Russia, Holland, Sweden, and Belgium.

Features of the family history that suggest mutations in *BRCA1* or *BRCA2* include having two or more relatives affected with early-onset breast or ovarian cancer, or both, with involvement of two or more generations in a pattern consistent with autosomal dominant inheritance. This can be through maternal or paternal relatives. A typical pedigree is shown in Figure 74.14. The likelihood of a mutation also varies with ethnic ancestry. For example, in an Ashkenazi Jewish family with two cases of breast cancer and one case of ovarian cancer, the chance of a *BRCA1* mutation is 75%, but in a non-Ashkenazi family with the same history, the probability is only 33%.⁷⁸ Models have been developed and validated to assist clinicians in estimating the probability of a mutation.⁷⁹

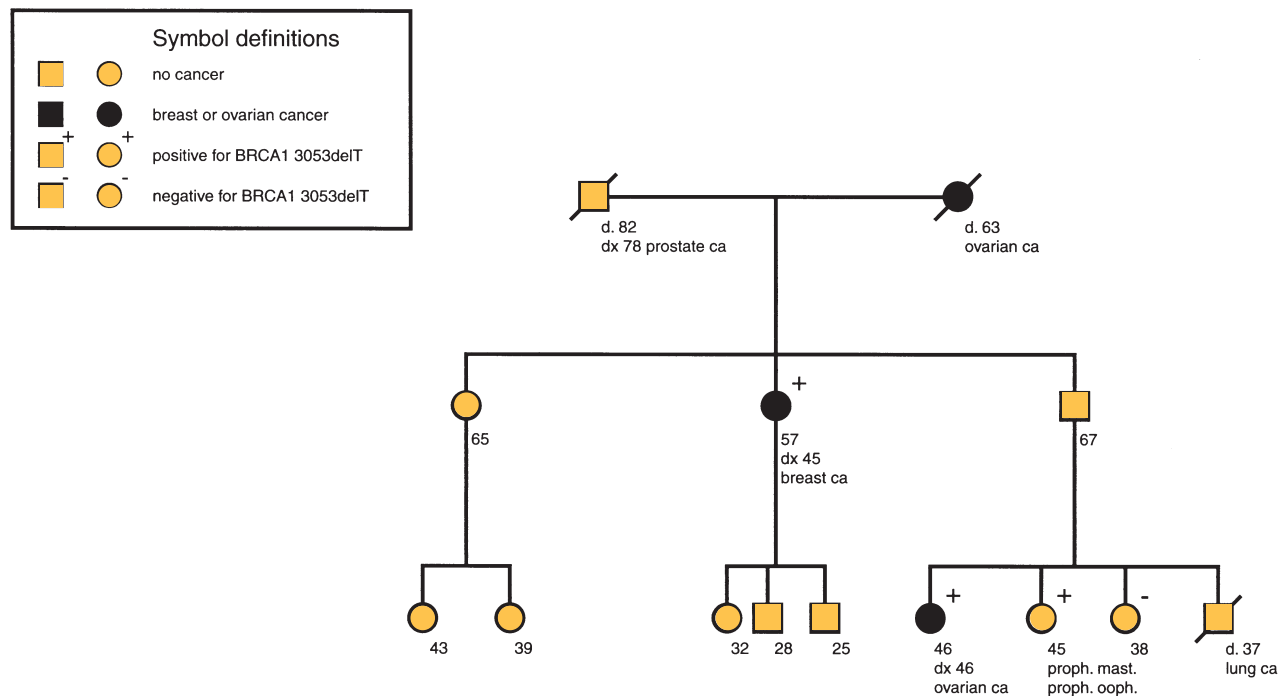

FIGURE 74.14. Pedigree of genetic breast cancer. The family illustrated in the pedigree carries a mutation of the *BRCA1* gene; multiple relatives are affected with breast and ovarian cancer.

Genetic testing for mutations of *BRCA1* and *BRCA2* is now a commercially available option for women with a family history suggestive of a genetic mutation. Genetic testing should always be preceded by a counseling session in which the complexities of genetic testing and the potential emotional and financial ramifications of test results are discussed. The information obtained from testing will be maximized by first testing a family member affected with breast or ovarian cancer, or both. If the affected person does not carry a mutation, testing an unaffected relative is unlikely to be informative.

Other, infrequent genetic breast cancer syndromes include the Li-Fraumeni syndrome, Cowden syndrome, and the Lynch syndromes. The Li-Fraumeni syndrome is associated with mutations in the tumor-suppressor gene *p53*, and is an autosomal dominant condition characterized by soft tissue sarcomas, osteosarcomas, brain tumors, leukemia, adrenocortical malignancies, and early-onset breast cancer.⁸⁰

For the majority of women with a family history of breast cancer that is not associated with an inherited mutation, the level of risk is much lower and rarely exceeds 30%.

Hormonal Factors

Numerous studies have linked breast cancer risk to the lifetime exposure to estrogens, as reflected by age at menarche, menopause and first pregnancy, and postmenopausal obesity.⁸¹ Conversely, women who undergo bilateral oophorectomy before menopause are at decreased risk, with the magnitude of benefit increasing as the age at oophorectomy decreases. In general, hormonal risk factors are associated with a RR in the range of 1.5 to 2.0. Studies of the effect of lactation on breast cancer risk have been inconclusive, but a long duration of lactation appears to reduce risk in premenopausal women.⁸²

In healthy women, there is no convincing evidence for an effect of oral contraceptive use on breast cancer risk, despite extensive study,⁸³ but use of combination postmenopausal hormone replacement therapy (estrogen plus progesterone) appears to be associated with a small increase in breast cancer risk, with higher risk associated with longer use.⁸⁴ For those with a personal history of breast cancer, there does appear to be an increased risk of recurrence with hormone replacement therapy.⁸⁵

Environmental and Lifestyle Factors

Exposure to ionizing radiation, whether from a nuclear explosion or medical procedure, increases breast cancer risk. The level of risk varies with age at exposure, being greatest for exposures in childhood and adolescence, and minimal for exposures after age 40. Patients who were treated with mantle irradiation for Hodgkin lymphoma in their adolescent or childhood years are the group at risk on the basis of radiation exposure most commonly encountered today.⁸⁶

Much attention has been devoted to the role of diet in breast cancer etiology, especially with respect to dietary fat intake. Prospective studies of fat consumption and breast cancer risk have failed to confirm a direct relationship, possibly because of the limited range of dietary fat in the typical American diet and the potential interaction between reproductive variables, menopausal status, and fat intake.^{87,88} Similar efforts to elucidate an association between breast cancer risk and other dietary factors such as red meat, vitamin D, calcium, phytoestrogens, and caffeine have been equally inconclusive.⁸⁹⁻⁹² Stronger evidence exists to support an association between alcohol intake and breast cancer risk.⁹³

Regular physical exercise appears to provide modest protection against breast cancer, particularly among postmenopausal

atypia are associated with a small increase in breast cancer risk (RR, 1.5 to 2.0). Proliferative lesions with atypia are uncommon, comprising only 3.6% of palpable breast masses and 7% to 10% of nonpalpable abnormalities. Atypical lesions are associated with a RR of 4.0 to 5.0, which increases to 9.0 when they are found in a woman having a first-degree relative with breast cancer.⁹⁶ As illustrated in Figure 74.15, however, breast cancer will have developed at 15 years in only 10% of women with atypical hyperplasia alone.

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS), first described by Foote and Stewart in 1941 as a favorable malignancy,⁹⁷ has been accepted as a risk factor for breast cancer since the mid-1980s. This paradigm shift was based on the unique biologic features of LCIS, which include a lack of clinical or radiographic findings, multifocality and bilaterality in up to 50% of cases, and clinical experience demonstrating the risk of subsequent breast cancer to be equal in both breasts, and lower than expected. Although invasive lobular carcinoma is more frequent after LCIS than in the general population, infiltrating ductal carcinoma is the most common histologic tumor type, casting further doubt upon the role of LCIS as a precursor lesion.^{98–104} The term *lobular intraepithelial neoplasia* (LIN), with lobular hyperplasia without atypia being described as grade 1 LIN, atypical lobular hyperplasia as grade 2 LIN, and LCIS as grade 3 LIN, was suggested with the intention of clarifying its role as a high-risk lesion rather than a malignancy; however, LCIS remains more commonly used in clinical practice. LCIS occurs predominantly in premenopausal women and is usually identified incidentally with other benign changes in women who undergo biopsy. Women diagnosed with grade 3 LIN or LCIS have a RR for breast cancer development ranging from 5.4 to 12.^{98–105} This translates in most studies to a risk for breast cancer development of about 1% per year (Table 74.7), and this risk persists indefinitely.

While historical series suggest that the increased risk of breast cancer is conferred equally to both breasts and subsequent cancers are equally likely to be infiltrating ductal or lobular carcinomas, recent evidence suggests that subsequent cancer is up to three times more likely in the ipsilateral breast, and the observed frequency of infiltrating lobular carcinoma (ILC) following a diagnosis of LCIS (50%) far exceeds the frequency of ILC observed in large series of unselected breast cancer patients (10% to 15%).^{106–108} These

observations, combined with emerging laboratory evidence suggesting phenotypic and genotypic similarities between coexisting LCIS and invasive lobular cancers,^{109,110} have reopened the debate over the malignant potential of LCIS and its possible role as a precursor lesion. To date, there is no direct clinical evidence that LCIS is a precursor lesion, and studies attempting to show an increased risk of local recurrence when LCIS is found in the lumpectomy specimen of patients undergoing breast conservation, particularly when LCIS is at the specimen margin, have failed to demonstrate a relationship between LCIS and local recurrence,^{111–116} arguing against its true malignant potential.

The recognition of histologic variants of LCIS, such as pleomorphic LCIS, with molecular profiles suggestive of a more aggressive biology¹¹⁷ and the broader spectrum of lesions now classified as lobular neoplasia based on immunohistochemical staining for e-cadherin, raises new questions regarding the biology of these lesions and appropriate clinical management.

CLINICAL ASSESSMENT OF RISK

Many factors that increase breast cancer risk have been identified in studies of large populations and are summarized in Table 74.8, but are of uncertain benefit in counseling the individual woman. Several of these have been integrated into a model to allow calculation of risk for an individual woman by Gail et al.¹¹⁸ These include age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, number of prior breast biopsies, and whether or not any of the biopsies showed atypical hyperplasia. This model calculates risk over a defined time interval, allows comparison with age-specific incidence figures, and predicts risk accurately in groups of women undergoing annual mammographic screening. It is a useful tool for counseling women who are concerned about their level of risk. It is not an appropriate model, however, for women at risk because of a strong family history of breast cancer, particularly early-onset breast cancer, or those with LCIS. A sample Gail model risk calculation is shown in Figure 74.16. A more appropriate risk model for women with strong family histories, which has not, however, been validated to the same extent as the Gail model, was described by Claus et al.¹¹⁹ and considers both the age at onset in affected relatives and the history of cancer in second-degree relatives.

MANAGEMENT OF THE HIGH-RISK WOMAN

Counseling women who are at high risk for breast cancer should include a discussion of the options for enhanced surveillance, chemoprevention, and prophylactic surgery. If a woman is at high risk secondary to a strong family history of breast cancer or very early onset of breast or ovarian cancer, genetic counseling should be offered. For patients with known or suspected *BRCA1* or *BRCA2* mutations, most experts suggest aggressive surveillance consisting of an annual mammogram, annual MRI, and clinical breast exam every 4 to 6 months beginning at age 25. For patients with a more moderate family history, annual mammographic screening and clinical breast exam should begin within 10 years of age of breast cancer diagnosis in a first-degree relative or age 40, whichever comes first.

The use of MRI screening for women at high risk is supported by the results of seven clinical trials demonstrating greater sensitivity of MRI as compared with mammography for the detection of breast cancer.¹²⁰ Participants in each of

these seven studies had either a documented *BRCA1* or *BRCA2* mutation, or a very strong family history of breast cancer. Some of the studies included women with a prior personal history of breast cancer. The cancer detection rate in these studies ranged from 1% to 9% (average 4%). Overall, the studies reported a high sensitivity for MRI, ranging from 71% to 100%, compared with 13% to 40% for mammography. Based on these studies, the American Cancer Society issued guidelines in 2007 recommending annual screening MRI in addition to annual screening mammography in women with a known *BRCA1* or *BRCA2* gene mutation, a lifetime risk of breast cancer exceeding 20%, or a history of mantle radiation for Hodgkin disease before the age of 30.¹²¹

The use of chemopreventive agents for breast cancer risk reduction should be individualized for each patient based on menopausal status, medical history, family history, and a quantified estimate of breast cancer risk. Tamoxifen (Nolvadex) and raloxifene (Evista) are both selective ER modulators (SERMs) that have been shown to reduce the risk of breast cancer. Tamoxifen has been used to treat breast cancer for more than 25 years. Data from treatment trials^{122,123} demonstrating that women taking tamoxifen for 5 years had a significantly reduced rate of contralateral breast cancer led to studies of tamoxifen as a chemopreventive agent for women at increased risk of breast cancer. The National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 prevention trial randomized 13,388 women at increased risk for breast cancer development to tamoxifen or placebo.¹⁰⁵ Risk was defined by the Gail model.¹¹⁸ Eligible women included those who were age 60 or older, or those between the ages of 35 and 59 years with a predicted 5-year breast cancer risk of 1.66% or more. After a median follow-up of 54.6 months, a 49% reduction in the risk for invasive cancer and a 50% reduction in the risk for noninvasive cancer were found in the tamoxifen group. The reduction occurred only in ER-positive tumors; the occurrence of ER-negative tumors was unchanged. Tamoxifen was of benefit in all age groups, in women at risk on the basis of a family history, and in those eligible for the study on the basis of other risk factors. Women at risk on the basis of LCIS and atypical hyperplasia had particular benefit, with risk reductions of 65% and 86%, respectively.¹²³ Updated results from the P-1 study based on 7 years of follow-up noted similar reductions in breast cancer incidence.¹²⁴ A meta-analysis of five completed tamoxifen prevention trials demonstrated a 38% reduction in breast cancer incidence in populations at varying levels of risk.¹²⁵

The most common side effects of tamoxifen were hot flashes and vaginal discharge. Participants who took tamoxifen had a 2.5 times greater risk for endometrial carcinoma than those in the placebo group, and postmenopausal women carried all of the excess risk. An increased risk for venous thrombosis, including pulmonary embolism, occurs in the postmenopausal women taking tamoxifen. The rate of pulmonary embolism in these women, however, was 1 in 1,000 annually. The presence of these competing risks, particularly in postmenopausal women, led to the search for other acceptable chemopreventive agents. The NSABP Study of Tamoxifen and Raloxifene (known as the STAR or P-2 trial) randomized 19,747 postmenopausal women at increased risk for breast cancer to either tamoxifen 20 mg/d or raloxifene 60 mg/d for 5 years. Raloxifene is a second-generation SERM that reduces the incidence of breast cancer in preclinical models and in clinical trials evaluating its use for the prevention of osteoporosis and heart disease in postmenopausal women.¹²⁶ Similar to the P-1 trial, increased risk was defined as a 5-year predicted breast cancer risk of 1.66% as determined by the Gail model or a personal history of LCIS treated by excision alone. After 6 years of follow-up, raloxifene was found to be equivalent to tamoxifen in reducing the incidence of invasive breast cancer (50% reduction) but with fewer side effects (Fig. 74.17).¹²⁷ Raloxifene was inferior to tamoxifen in reducing the risk of ductal carcinoma in situ. The reason for this selective effect remains unclear.

FIGURE 74.16. Breast cancer risk assessment according to the Gail model. This woman's 5-year risk for the development of breast cancer is 1.6%, and her lifetime risk is 18%.

FIGURE 74.17. Both tamoxifen and raloxifene when taken for 5 years in the National Surgical Adjuvant Breast and Bowel Project P-2 (STAR trial) were equally effective at reducing the risk of invasive breast cancer.

The incidence of uterine cancer was lower in the raloxifene arm, with the difference approaching statistical significance, but more than half the women in the STAR trial had previously undergone a hysterectomy, limiting the ability to assess the effect of raloxifene on the uterus. Pulmonary embolism and deep venous thromboses occurred less often in the raloxifene group (RR, 0.70); however, there was an equal number of strokes and transient ischemic attacks. Rates of fracture were virtually identical in the two treatment arms, and there were no statistically significant differences in patient-reported quality-of-life outcomes, although specific symptoms showed significant differences.¹²⁸ When counseling postmenopausal women, differences such as the frequency of hot flashes and sexual side effects may be an important factor

in determining which drug is most appropriate for an individual patient.

Aromatase inhibitors (AIs) block the conversion of androgens to estrogens by the aromatase enzyme and lower circulating estrogen levels. AIs have proven effective in breast cancer treatment among postmenopausal women with hormone-sensitive tumors, and clinical trial data from three studies show that AIs decrease the incidence of contralateral breast cancers by 37% to 55%.¹²⁹⁻¹³¹ Clinical trials assessing the chemopreventive potential of AIs among women at increased risk for breast cancer are currently under way.

Surgical options for women at increased risk for breast cancer include prophylactic mastectomy and prophylactic salpingo-oophorectomy. Both subcutaneous and total (simple) mastectomies have been used for breast cancer prevention; however, neither provides 100% protection. The development of carcinoma in residual breast tissue has been reported after both types of surgery. The efficacy of prophylactic mastectomy in a group of high-risk women was defined in a study of 639 women from the Mayo Clinic, of whom 90% underwent subcutaneous mastectomy and 10% received total mastectomy.¹³² At a median of 14 years, prophylactic mastectomy reduced the risk for breast cancer by 90%. Trials in women at risk on the basis of *BRCA1* and *BRCA2* mutations have confirmed a similar efficacy for prophylactic mastectomy in this group. Prophylactic mastectomy is a prevention option that should be undertaken only after a complete risk assessment, consultation with a reconstructive surgeon, and a thorough discussion of management alternatives. Women should be advised of their level of risk and assisted in determining if that level of risk is unacceptable to them, rather than being told to undergo prophylactic surgery. When prophylactic mastectomy is performed, the procedure should be a total mastectomy extended to the same anatomic limits as a therapeutic mastectomy. Patients undergoing prophylactic mastectomy are ideal candidates for a skin-sparing approach to facilitate immediate breast reconstruction (Fig. 74.18). The role of nipple-sparing mastectomy for prophylaxis remains controversial.

FIGURE 74.18. Skin-sparing mastectomy. A: The only skin removed was the nipple-areola complex. B: Cosmetic outcome after bilateral skin-sparing mastectomy and transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

Bilateral salpingo-oophorectomy as a risk reduction strategy is generally limited to women with *BRCA1* and *BRCA2* mutations. In this population prophylactic salpingo-oophorectomy reduces the risk of breast cancer by 50%^{133,134} and reduces the risk of ovarian cancer by 98%.

DUCTAL CARCINOMA IN SITU

Ductal carcinoma in situ (DCIS), also known as *intraductal carcinoma*, is a distinct entity from LCIS, the other lesion classified as noninvasive breast cancer, with differences in both clinical presentation and biologic potential. DCIS is characterized by a proliferation of abnormal, presumably malignant epithelial cells that are confined within the basement membrane of the mammary ductal-lobular system (Fig. 74.19).

Presentation

Ductal carcinoma in situ has a variety of clinical presentations: palpable mass, pathologic nipple discharge, or Paget disease of the nipple, all of which are relatively uncommon. The overwhelming majority of palpable breast cancers are invasive carcinoma; fewer than 2% are DCIS. Today, clustered microcalcifications on a mammogram are the most frequent presentation of DCIS, although approximately 10% of nonpalpable masses may also be DCIS. In many reports of biopsies performed for mammographic abnormalities, DCIS accounts for 30% to 50% of the malignancies identified. The number of cases of DCIS between 1975 and 2004 increased by 560% as screening mammography became widely adopted.¹³⁵ This increase was observed in both white and black women, and in those over and under 50 years of age, DCIS may also lack both clinical and mammographic findings and be discovered incidentally in a biopsy done for other indications. Of lesions initially diagnosed as DCIS by large-gauge vacuum-assisted core biopsy, 15% to 20% will be found to contain invasive carcinoma when completely excised. Invasive carcinoma is most frequently found in large, high-grade DCIS lesions.¹³⁶

Pathology

Ductal carcinoma in situ has traditionally been classified on the basis of architectural pattern as comedo, cribriform, micropapillary, papillary, or solid. Because a mixed architectural pattern occurs in as many as 30% to 60% of DCIS

FIGURE 74.19. Photomicrograph of ductal carcinoma in situ. The abnormal cells do not cross the ductal basement membrane. The necrotic debris in the center of the duct is responsible for the calcification visible on mammography.

lesions, however, the utility of this classification system is limited. Newer systems classify DCIS lesions on the basis of nuclear grade and necrosis, and usually recognize three groups of lesions: high, intermediate, and low grade. Multiple systems have been proposed, but their reproducibility and ability to predict the behavior of DCIS remain to be proved.

Management

Mastectomy, excision and irradiation (radiation therapy [RT]), and excision alone have all been proposed as management strategies for DCIS because of uncertainty about the natural history of the disease. Mastectomy is a curative treatment for approximately 98% of patients with DCIS, regardless of lesion size or grade.^{137,138} Treatment failure after mastectomy for DCIS is thought to be a consequence of unrecognized invasive carcinoma.

Although mastectomy is an effective treatment for DCIS, it is a radical approach for a lesion that may not progress to invasive carcinoma during a patient's lifetime and is too small to be detected clinically. The use of BCT with excision and RT for invasive carcinoma (see section on local management of stages I and II breast cancer) has stimulated greater interest in the use of this approach for DCIS. No randomized trial has ever compared the treatment of DCIS by mastectomy with treatment by excision and RT. A large number of clinical studies have demonstrated that the local recurrence rate after treatment with excision and RT is 10% to 15% of cases after 10 years,¹³⁷⁻¹⁴¹ and that approximately half of the local recurrences are invasive carcinoma. Deaths from DCIS are rare; 14 breast cancer deaths occurred in 814 patients followed for 8 years after treatment with excision and RT.¹⁴⁰

Because DCIS is a local problem in the breast and all DCIS does not progress to invasive carcinoma during a patient's lifetime, some authors have suggested that DCIS can be treated by wide excision alone. Four prospective, randomized trials have compared the outcome of excision alone to excision and RT, and the results are summarized in Table 74.9. Despite differences in study design, the trial results are remarkably similar.¹⁴²⁻¹⁴⁵ The studies demonstrate that the use of RT reduces ipsilateral breast tumor recurrence by 50% to 60%, and this reduction persists through 12 years of follow-up in the NSABP B-17 study. The use of RT reduces both invasive and noninvasive recurrences; with the use of RT, the annual rate of invasive recurrence is 0.5% to 1.0%. In patients treated with excision alone or excision and RT, approximately 50% of recurrences are invasive and 50% are DCIS. No survival benefit for RT has been observed. In a more detailed pathologic analysis,¹⁴⁵ the greatest benefits of RT were in the patients at highest risk for recurrence (those with comedo necrosis and uncertain margins), but even in the most favorable subgroup (absent or slight comedo necrosis, clear margins), the use of RT reduced the absolute incidence of breast recurrence by 7% at 8 years. A retrospective study has suggested that excision of DCIS with a 1-cm margin of normal breast tissue eliminates the need for RT,¹⁴⁶ but attempts to prospectively duplicate this observation have been unsuccessful.¹⁴⁷

Treatment selection for the patient with DCIS begins with a careful evaluation of the extent of the DCIS lesion by means of magnification mammography. Standard two-view mammography significantly underestimates the extent of well-differentiated DCIS.¹⁴⁸ If the extent of the DCIS is too large, relative to the patient's breast size, to allow a cosmetically acceptable breast-conserving approach, the patient should be counseled about the options of mastectomy alone or mastectomy with immediate breast reconstruction. In patients with localized DCIS suitable for a breast-conserving approach, the decision regarding the need for RT should be made based on the estimated risk for recurrence and the patient's attitude toward

TABLE 74.9

RESULTS

RESULTS OF RANDOMIZED TRIALS OF RADIOTHERAPY IN DUCTAL CARCINOMA IN SITU

risk. Patients with larger tumors, high-grade lesions, and close margins appear to derive the greatest benefit from RT. It also appears that younger women are at higher risk for recurrence than their older counterparts.^{142,149} However, even patients with small, low-grade lesions appear to benefit from RT,¹⁴²⁻¹⁴⁵ and it is in this low-risk subgroup that the patient's attitude toward risk becomes important.

Tamoxifen is of benefit in reducing the risk for subsequent invasive carcinoma in patients with DCIS. In NSABP B-24,¹⁴⁹ 1,804 women with DCIS treated by excision and RT were randomized to tamoxifen or placebo for 5 years. Tamoxifen caused a reduction in the incidence of all breast cancer events from 17% to 10.0% ($p = 0.01$). The benefit of tamoxifen was observed in women over and under age 50, and in those with negative and positive margins. A benefit for tamoxifen was also observed whether or not comedo necrosis was present in the tumor. A subset analysis of 676 patients for whom ER status could be determined was performed retrospectively. The benefit of adding tamoxifen to RT in reducing all breast cancer events was 59% in ER-positive women, compared with 37% in the overall patient population. There was little benefit for tamoxifen in ER-negative DCIS, and its use is not warranted in these patients. The UK trial¹⁴³ compared treatment with excision alone with excision plus tamoxifen. After a median follow-up

of 53 months, there were no differences in the rate of local recurrence between groups. The findings of this study indicate that tamoxifen is not a replacement for RT. The effects of RT and tamoxifen in the NSABP B-17 and B-24 trials^{140,149} are illustrated in Figure 74.20. The decision to use RT, tamoxifen, or both in the patient with DCIS will depend on the patient's personal level of risk and attitude toward small benefits from therapeutic intervention, but both should be considered. Identification of markers that predict which women with DCIS will develop an invasive recurrence is a research priority that will greatly improve our ability to tailor treatment to an individual's level of risk.

Axillary nodal involvement in DCIS is rare and presumed to be due to unrecognized invasive carcinoma. In NSABP B-17 and B-24, the axillary recurrence rates, regardless of treatment, were less than 1 per 1,000 patient-years of follow-up.¹⁵⁰ For this reason, axillary staging is not routinely indicated in the patient with a diagnosis of DCIS. Most would agree that sentinel node biopsy should be performed in patients undergoing mastectomy for DCIS since the opportunity for sentinel node biopsy is lost if not performed at the time of mastectomy. In addition, many of these patients have large areas of DCIS where the risk of sampling error after a needle biopsy diagnosis of DCIS is highest.

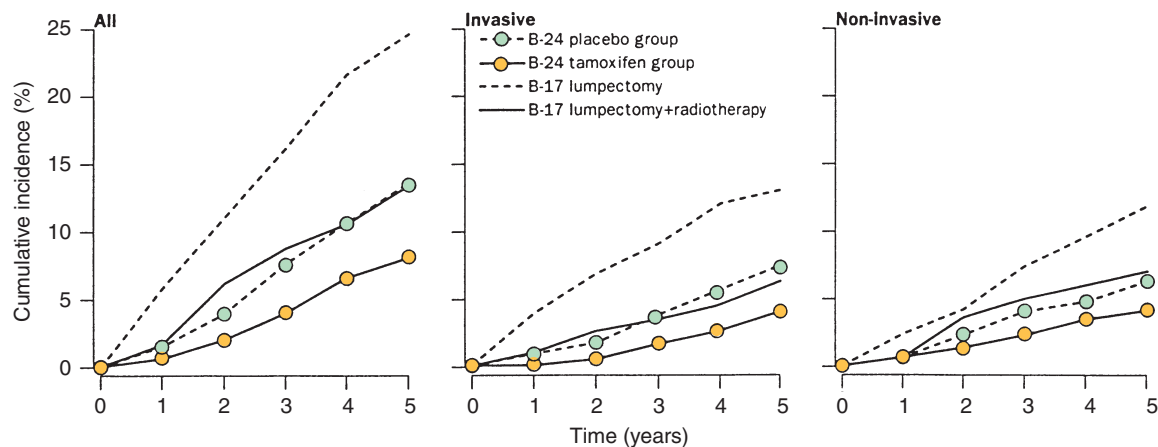

FIGURE 74.20. Benefits of radiation therapy and tamoxifen in ductal carcinoma in situ. The cumulative incidence of breast cancer events in the ipsilateral and contralateral breasts for patients treated in the National Surgical Adjuvant Breast and Bowel Project B-17 and B-24 trials is shown. The reduction in recurrence is greatest for patients receiving radiotherapy and tamoxifen.

BIOLOGY AND NATURAL HISTORY OF BREAST CANCER

Breast cancer is a disease characterized by marked heterogeneity among patients and a long natural history. This is evident in the Middlesex Hospital series, in which Bloom et al.¹⁵¹ reported the outcome of 250 patients with breast cancer observed without treatment between 1805 and 1933. Patients were generally admitted for advanced disease, with only 2% having stage II disease, 23% having stage III, and 74% having stage IV. Only 39% presented within 1 year of their first symptom. Despite this, 18% of patients receiving no treatment survived 5 years, and 4% survived 10 years. The mortality was constant over time, with approximately 25% of patients who were alive at the beginning of any given year dying during that year. In modern series, patients with varying annual hazards of death can also be identified, and these remain constant for at least 10 years after the diagnosis. For this reason, some have concluded that breast cancer is never cured, and that if death from other causes did not intervene, cancer eventually would recur in all patients. Although this may be true in the abstract, from a practical point of view, failures more than 20 years after treatment are rare, and many patients have a normal life expectancy after breast cancer treatment. The clinical variations in breast cancer are believed to reflect variable genetic changes that result in the disease.

The initial clinical understanding of breast cancer, as articulated by Halsted,¹⁵² was one of orderly disease progression, suggesting that en bloc extirpation of the primary tumor with a wide margin of normal tissue (i.e., the breast) and the draining lymphatics was the most likely strategy to cure breast cancer. Over time, it became clear that the majority of women with breast cancer were not cured by radical mastectomy. Recognition of this fact initially led to larger operations, such as the extended radical mastectomy to remove more of the lymphatic drainage of the breast. When these procedures failed to improve survival, however, a dramatic shift in thinking occurred. In the new disease paradigm, championed by Bernard Fisher,¹⁵³ most breast cancer was considered to be systemic at the time of diagnosis, so that the extent of locoregional treatment would have little impact on survival from breast cancer. Acceptance of this concept led to the adoption of the modified radical mastectomy, and subsequently breast-conserving surgery, for the treatment of stages I and II breast cancer, in addition to the widespread use of adjuvant chemotherapy and hormonal therapy.

More recently, a spectrum hypothesis has been advanced suggesting that breast cancer exists in a local, locoregional, and systemic form, and that metastasis can occur during the clinical course of the disease.¹⁵⁴ In this paradigm, effective locoregional treatment does contribute to survival, a concept supported by the Early Breast Trialists Collaborative Group overview of randomized trials of local therapy in breast cancer.¹⁵⁵ In this overview, treatments that decreased local failure rates at 5 years by 10% or more, whether by surgery or RT, were associated with a statistically significant improvement in disease-specific survival at 15 years. In these studies, it appears that for every four local recurrences prevented, one breast cancer death is avoided, although this ratio may change as more effective systemic therapies become available.

capability to metastasize. Any breast lesion that is surgically removed should be considered potentially malignant. Breast biopsy specimens should be oriented in the operating room and inked before sectioning so that the margin status can be assessed. The pathologic evaluation of a breast tumor should routinely include size, histologic type, grade, margin status, hormone receptor, and HER2 status.

Histologic Type

Infiltrating ductal carcinoma is the most common type of breast carcinoma, accounting for 65% to 80% of all cases of breast cancer. Microscopically, infiltrating ductal carcinomas vary widely in appearance and often have features of other histologic subtypes of breast cancer, with areas of lobular, medullary, or tubular differentiation. For prognostic purposes, these mixed tumors are considered to be infiltrating ductal carcinomas.

Infiltrating lobular carcinoma is the second most frequently encountered subtype of invasive carcinoma. Approximately 10% of cancers are classified as lobular. Histologically, lobular cancers grow as a single file of malignant cells that tend to be arranged circumferentially around ducts and lobules. Because of this growth pattern, they are often difficult to recognize on clinical examination and mammography because they may not produce the distinctive mass lesions characteristic of infiltrating ductal carcinomas. Infiltrating lobular carcinoma has been said to have a rate of bilaterality as high as 30% to 50%. When patients with LCIS are excluded from consideration, however, the incidence of contralateral breast cancer in patients with infiltrating lobular carcinoma differs little from that in patients with ductal carcinoma. In one study of 4,748 patients, a contralateral cancer had developed after 5 years in 5.3% of patients with infiltrating lobular cancer, and in 4.0% of those with infiltrating ductal tumors.¹⁵⁶ Thus, the routine use of bilateral mastectomy for patients with tumors of lobular histology cannot be justified. Lobular carcinoma is more likely to metastasize to the intra-abdominal viscera, uterus, ovaries, and peritoneal surfaces than other histologic types of breast carcinoma. Most studies have found no difference in survival between patients with infiltrating ductal and those with lobular carcinoma after stratification for appropriate prognostic factors.

Favorable histologic subtypes of breast carcinoma include pure tubular and mucinous carcinoma. Tubular carcinomas form normal-appearing breast ductules or tubules. At least 75% of a tumor must be tubular to be classified in this subtype. Tubular carcinomas are uncommon, accounting for 2% or fewer of all cancers, although they are more frequent in women undergoing screening mammography. Their significance lies in their excellent prognosis. Nodal metastases are extremely rare in tubular carcinomas smaller than 1 cm, and even when nodal metastases do occur, the prognosis is much better than that for ductal or lobular carcinoma at the same stage. Mucinous or colloid carcinomas are also uncommon. They are characterized by relative acellularity and large pools of extracellular mucus. The prognosis is similar to that for tubular carcinoma. Medullary carcinoma is another variant of infiltrating ductal carcinoma with a favorable prognosis, although this is less well recognized than in tubular and mucinous tumors, perhaps because of the aggressive microscopic appearance of medullary carcinoma. The tumor cells have large pleomorphic nuclei and a high mitotic rate, and are associated with an intense lymphoplasmacytic infiltrate. Grossly, the tumors are well circumscribed and may be mistaken for benign lesions. Medullary carcinomas are less likely to be associated with axillary nodal metastases than ductal or lobular carcinomas of the same size, and survival is also better. Other histologic types of breast cancer account for fewer than 2% of all cancers.

INVASIVE CARCINOMA

Pathology

Invasive carcinomas are defined as those in which tumor cells have crossed the basement membrane and have the biologic

Grading Systems

The grade of a carcinoma is an estimate of differentiation. It may be histologic or nuclear. Nuclear grading is a cytologic assessment of the similarity of tumor nuclei to the nuclei of normal cells. The nuclear grade is usually reported as well differentiated, intermediate, or poorly differentiated. The histologic grade considers not only the cytologic differentiation but also the growth pattern of the carcinoma. The extent of tubule formation, nuclear hyperchromasia, and the mitotic index are assessed. In one of the most widely used systems, the Elston modification of the Scharf-Bloom-Richardson classification, each of these three elements is scored on a scale of 1 to 3, with a resultant classification of grade 1 (score of 3 to 5), grade 2 (score of 6 or 7), or grade 3 (score of 8 or 9).¹⁵⁷ Approximately 19% of the 2,000 cases reviewed by Elston and Ellis¹⁵⁷ were grade 1, 34% were grade 2, and 47% were grade 3. A study of the molecular phenotypes associated with histologic grade demonstrated distinct genetic profiles for grade 1 and grade 3 tumors, but a profile for grade 2 tumors could not be identified. Instead, tumors classified as grade 2 were found to have the genetic profile of grade 1 or grade 3 tumors, calling into question the existence of a grade 2 group as a distinct prognostic group.¹⁵⁸

Hormone Receptors and HER2

The concept of an estrogen receptor was described by Jensen and Jacobsen in 1962,¹⁵⁹ based on the observation that estrogens tagged with radioactive isotopes are preferentially concentrated in the estrogen target organs of animals (i.e., breast, uterus, vagina) and in human breast cancers. Subsequently, a second hormone receptor, the progesterone receptor (PR), was identified. ERs and PRs belong to a superfamily of nuclear hormone receptors that function as transcription factors when bound to their respective ligands. Approximately 70% of breast carcinomas are hormone receptor positive; well-differentiated tumors and those occurring in older postmenopausal women have the highest rates of receptor positivity. Approximately 60% of patients with ER-positive tumors respond to endocrine therapy, but only 5% to 10% of patients with ER-negative tumors do so, and responses probably result from false-negative receptor results.¹⁶⁰ It is now apparent that there are two receptors for estrogen, ER α (the classic receptor identified by Jensen) and ER β , identified by Gustaffson's laboratory in 1996.¹⁶¹ At present, the clinical significance of ER β in breast cancer management is uncertain. Tumor ER α and PR content is measured by immunohistochemical techniques. Determination of hormone receptor status is a critical part of the pathologic analysis of breast tumors and is used to ascertain whether the patient is a candidate for hormonal therapy (see section on adjuvant systemic therapy).

The HER2 gene, also known as HER2/neu or c-erbB2, is located on chromosome 17q. HER2 is a member of the epidermal growth factor receptor (EGFR) family of transmembrane tyrosine kinases and is normally involved in regulation of cell proliferation. The HER2 gene is a proto-oncogene, a normal gene with the potential to become an oncogene upon molecular alterations, such as mutation, amplification, or overexpression of its protein product. The HER2 protein is overexpressed and/or its gene is amplified in ~20% of invasive breast cancers. HER2 amplification is associated with a more aggressive phenotype and predicts for response to trastuzumab therapy, a recombinant humanized monoclonal antibody specific for the external region of HER2¹⁶² (see section on adjuvant systemic therapy). Immunohistochemistry for membrane-bound HER2 protein is most commonly employed for semiquantitative

analysis of staining (0, 1+, 2+, or 3+) followed by fluorescence in situ hybridization (FISH) for confirmation of gene amplification in cases scored as positive (2+ or 3+).¹⁶³

Molecular Subtyping

Over the last decade, advances in DNA microarray technology and sophisticated genomic analyses have led to the development of classification systems of breast cancer based on gene expression profiles. As such, breast cancer is increasingly being recognized as a heterogeneous family of diseases with implications for both tumor biology and treatment. First described in the seminal papers by Perou and Sorlie,^{164,165} and subsequently validated by others,^{166,167} the intrinsic breast cancer subtypes have been identified as HER2 positive, ER positive luminal A, ER positive luminal B, and basal-like or "triple negative." These intrinsic subtypes, which characterize the primary tumor and remain constant through the metastatic process, have been shown to be prognostic for clinical outcome as well as predictive of response to therapy, and provide important insights into tumor biology.

The basal-like group was named for the higher expression of genes characteristic of normal basal cells of breast epithelium including keratins 5, 14, or 17; HER1 (epidermal growth factor receptor); and smooth muscle actin.¹⁶⁴ Basal-like cancers are generally high-grade, poorly differentiated tumors with a poor prognosis. They are predominantly negative for ER, PR, and HER2, and clinical adoption of this breast tumor classification uses immunohistochemical "triple negativity" as the most practical surrogate for the identification of basal-like tumors. Basal-like tumors are more common in younger women, women of African descent,¹⁶⁸ and carriers of *BRCA1* germline mutations.

Clinical Evaluation and Staging

The extent of the preoperative workup should be guided by the clinical stage of the disease and the patient's symptoms. Patients with DCIS do not require screening for metastatic disease. Bone scans are frequently used as a preoperative screening test for patients with invasive cancer, but in a large review, the incidence of occult bony metastases detected by scanning in patients with stage I or II disease was less than 5%.¹⁶⁹ False-positive results are frequent, especially in older women. In asymptomatic women with stage III disease, 8.3% had bony metastases. The yield of liver screening studies is less than 1%, even for women with stage III disease, and the test is of little benefit in preoperative evaluation. Positron emission tomography (PET) scans are also not indicated in the routine preoperative evaluation of asymptomatic women.

Serum tumor markers have not been shown to be of value preoperatively. Studies of carcinoembryonic antigen, CA15-3, CA27.29, and the shed extracellular domain of erbB2 do not demonstrate sufficient sensitivity or specificity to indicate or exclude the presence of occult metastatic disease.

Staging refers to the grouping of patients according to the extent of their disease. The stage is useful in (a) determining the choice of treatment for an individual patient, (b) estimating prognosis, and (c) comparing the results of different treatment programs. Staging can be based on either clinical or pathologic findings.

Currently, the staging of cancer is determined by the American Joint Committee on Cancer (AJCC). The AJCC system is a clinical and pathologic staging system based on the TNM (tumor, node, metastasis) system.⁷

The clinical stage is based on all the information available before the first definitive treatment is administered. This

TABLE 74.10**STAGING****TUMOR, NODE, METASTASIS (TNM) CLASSIFICATION FOR BREAST CANCER STAGING**

TNM DEFINITIONS			
Primary Tumor			
Tx	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ, ductal or lobular or Paget disease of the nipple with no tumor		
T1	Tumor 2 cm or less in greatest dimension		
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension		
T3	Tumor more than 5 cm in greatest dimension		
T4	Tumor of any size with direct extension to the chest wall (not including pectoralis muscle), skin edema, skin ulceration, satellite skin nodules, or inflammatory carcinoma		
Regional Lymph Nodes (pathologic)			
Nx	Nodes cannot be assessed		
N0	No regional node metastases histologically, no additional examination for isolated tumor cells (ITCs)		
N1	Metastasis to one to three axillary nodes or in internal mammary (IM) nodes with microscopic disease detected by sentinel node biopsy, which is not clinically apparent		
N2	Metastases in four to nine axillary nodes or in clinically apparent IM nodes in the absence of axillary node metastasis		
N3	Metastases in 10 or more axillary nodes, or in infraclavicular nodes, or in IM nodes in the presence of one or more positive axillary nodes; or in more than three axillary nodes with IM metastases, or in supraclavicular nodes		
Distant Metastases			
Mx	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
STAGE GROUPING			
Stage 0	Tis	N0	M0
Stage I	TI	N0	M0
Stage IIA	T0	N1	M0

includes the findings from physical examination, imaging studies, operation, and pathologic examination of the breast or other tissues. The clinical stage is useful in selecting and evaluating therapy.

The pathologic stage (designated pTNM) is based on all the data used for clinical staging in addition to data derived from the pathologic examination of the primary carcinoma and axillary lymph nodes. A tumor cannot be evaluated for pathologic staging (pTX) if excision of the primary carcinoma reveals tumor in any margin of resection by gross pathologic examination. The pathologic stage provides the

most precise data to estimate the prognosis and calculate the end result. The current staging system is given in Table 74.10.⁷

Local Management of Stage I and Stage II Breast Cancer

The goal of the local therapy of breast cancer is to eradicate all clinically evident tumor in the breast and axillary lymph nodes. In the breast, this can be accomplished with a total

mastectomy, a total mastectomy with immediate breast reconstruction, or BCT, which consists of removal of the primary tumor with a margin of normal tissue and RT. Six modern prospective, randomized trials have compared mastectomy with BCT and have demonstrated no survival differences, even after long-term follow-up (Table 74.11).^{170–175} Mastectomy alone has never been compared with mastectomy and reconstruction in a randomized trial, but there is no reason to suspect that reconstruction would decrease survival. In the absence of survival differences, the role of the surgeon is to identify medical contraindications to the procedures and to counsel the patient regarding what is involved in each one.

- 9** Mastectomy alone has never been compared with mastectomy and reconstruction in a randomized trial, but there is no reason to suspect that reconstruction would decrease survival. In the absence of survival differences, the role of the surgeon is to identify medical contraindications to the procedures and to counsel the patient regarding what is involved in each one.
- 10 Breast-conserving Therapy.** For BCT to be successful, three conditions must be met. It must be possible to (a) reduce the tumor burden to a microscopic level likely to be controlled by irradiation, (b) safely deliver radiation therapy, and (c) promptly detect local recurrence. The contraindications to BCT arise logically from these conditions. In 1992, a joint committee of the American College of Surgeons, American College of Radiology, College of American Pathologists, and Society of Surgical Oncology developed guidelines for BCT. These were updated in 2007 and are listed in Table 74.12.¹⁷⁶

The incidence of the contraindications to BCT in the breast cancer population determines the number of patients who are advised to undergo mastectomy for medical reasons. Morrow et al.¹⁰ reported a study in which a multidisciplinary team of physicians prospectively evaluated 456 patients with DCIS, clinical stage I breast cancer, or clinical stage II breast cancer between 1988 and 1991. Medical contraindications to breast preservation were present in only 26% of the patients, and the incidence and type of contraindications varied significantly by stage, with only 10% of patients with stage I disease having contraindications to BCT.

In an effort to increase the number of patients eligible for breast conservation, the use of neoadjuvant chemotherapy to shrink the primary tumor before surgical therapy has been studied.¹⁷⁷ In a large randomized trial, NSABP protocol B-18, 1,523 patients with tumors of any size were randomized to receive four cycles of doxorubicin (A) and cyclophosphamide (C) either preoperatively or postoperatively.¹⁷⁸ All patients over age 50 received tamoxifen. A reduction in tumor diameter of 50% was noted clinically in 80% of the patients, and in 37%, no tumor could be felt after chemotherapy. However, only one fourth of the patients thought to be complete responders had no tumor identified microscopically after surgery.

Significant axillary down-staging also occurred, with pathologically negative nodes in 60% of the neoadjuvant group and in 42% of the postoperative adjuvant group ($p < 0.001$). Despite these impressive response rates, the rate of breast conservation increased by only 8%, from 60% to 68%. In a subsequent study, the addition of docetaxel to AC treatment preoperatively increased the clinical complete response rate from 40.1% to 63.6% ($p < 0.001$) and the pathologic complete response rate from 13.7% to 26.1% ($p < 0.001$).¹⁷⁹ Despite this increase in response rate, the use of BCT did not differ between patients receiving preoperative AC and those receiving AC plus Taxotere. This is probably because of the inability of the physical examination and imaging studies to reliably predict the degree of pathologic response. To date, neoadjuvant therapy has not been shown to improve survival in comparison with therapy given postoperatively.

TABLE 74.12 INDICATIONS/CONTRAINDICATIONS

CONTRAINDICATIONS TO BREAST-CONSERVING THERAPY IN INVASIVE CARCINOMA

ABSOLUTE CONTRAINDICATIONS

- Two or more primary tumors in separate quadrants of the breast
- Persistent positive margins after reasonable surgical attempts
- Pregnancy is an absolute contraindication to the use of breast irradiation. When cancer is diagnosed in the third trimester, it may be possible to perform breast-conserving surgery and treat the patient with irradiation after delivery.
- A history of prior therapeutic irradiation to the breast region that would result in re-treatment to an excessively high radiation dose
- Diffuse malignant-appearing microcalcifications

RELATIVE CONTRAINDICATIONS

- A history of scleroderma or active systemic lupus erythematosus
- Large tumor in a small breast that would result in cosmesis unacceptable to the patient. In this circumstance, preoperative chemotherapy should be considered.
- Very large or pendulous breasts if reproducibility of patient setup and adequate dose homogeneity cannot be ensured

In addition to the medical contraindications to BCT discussed earlier, patient desire is another indication for mastectomy. Not all women who are eligible for BCT opt for this therapy. In one study, greater patient involvement in the decision-making process was associated with a significantly higher mastectomy rate than when the surgeon was the primary decision maker.¹⁸⁰

The amount of breast tissue to be resected in a lumpectomy to minimize the risk for local recurrence while optimizing the cosmetic appearance remains a major issue. There is no consensus on what constitutes an adequate margin for a lumpectomy. The only microscopic margin definition used in randomized trials has been tumor cells not touching ink. There is little convincing evidence that wider margins reduce the risk of local recurrence. Studies have shown that the risk of residual tumor varies with the histology of the primary tumor, being lowest in pure infiltrating ductal carcinoma and highest in infiltrating ductal carcinoma with an extensive intraductal component (EIC); the risk in infiltrating lobular carcinoma falls between the other two.¹⁸¹ These studies indicate that the ideal balance between cosmesis and local failure is unlikely to be achieved by resecting the same amount of breast tissue in all patients. Magnification mammography is essential to identify the extent of the tissue that must be resected, and it allows large “quadrantectomy”-type resections to be reserved for patients with multifocal disease. With the use of physical examination and magnification mammography, the patients who can undergo breast conservation can be identified with a success rate higher than 95%.¹⁸² The extent of surgical resection is the major determinant of cosmetic outcome, and approximately 90% of patients treated with conservative resection rate their cosmetic outcome as excellent or good (Fig. 74.21).

Local recurrence of tumor in the breast after BCT has been the subject of many studies. Local recurrence may be a consequence of inappropriate patient selection, inadequate surgery or RT, or biologic characteristics of the tumor. The presence of tumor at the margin of resection significantly increases the risk for local recurrence, as does the use of radiation doses to the whole breast of less than 4,500 to 5,000 cGy. Six randomized trials have attempted to identify a subgroup of patients with invasive carcinoma who do not require RT. All have shown a large reduction (average, 75%) in the rate of local recurrence with RT,¹⁸³ and RT should be considered a standard part of BCT for invasive carcinoma. This is particularly true since the 2005 overview analysis¹¹¹ of trials of local therapy has demon-

strated that absolute improvements in local control of more than 10% at 5 years, whether obtained by surgery or radiation therapy, are associated with statistically significant reductions in breast cancer mortality 15 years after diagnosis. Studies are now ongoing to evaluate the efficacy of partial breast irradiation to the quadrant of the tumor on local control. Patient factors, such as young age, have also been associated with an increased risk for local failure after BCT. In contrast, a family history of breast cancer does not increase local failure rates. In women with mutations of *BRCA1* or *BRCA2*, the risk of new second primary cancers is increased in both breasts, but the risk of local failure does not seem to be elevated.¹⁸⁴ A number of tumor factors, such as size and involvement of axillary lymph nodes, that are strong predictors of the risk for distant recurrence are not associated with the risk for recurrence in the breast. Histologic tumor type also is not a risk factor, and studies have shown that recurrence rates after excision of infiltrating lobular carcinoma to negative margins do not differ from those after excision of infiltrating ductal tumors. Most studies also indicate that histologic grade is not predictive of recurrence. Some studies have identified lymphatic invasion at the primary tumor site as a risk factor, but this has also been shown to be a risk factor for local recurrence after mastectomy.

In the past, an EIC, defined as the presence of intraductal carcinoma both within an infiltrating ductal carcinoma and in adjacent grossly normal breast tissue, was thought to be associated with an increased risk for local, but not distant, recurrence. More recent studies indicate that when EIC-positive tumors are excised to negative margins, local failure rates are similar to patients with EIC-negative tumors.¹⁸⁵ The use of adjuvant chemotherapy or tamoxifen in patients who have received breast RT reduces the risk for breast recurrence by approximately 50%. In modern series, local failure rates of 4% to 8% at 10 years are commonly reported in patients receiving RT plus systemic therapy. The information on factors associated with local recurrence suggests that two types of recurrences develop after BCT. One type of recurrence represents a heavy tumor burden in the breast that is not controlled by breast irradiation. This type of recurrence can be minimized by meticulous patient selection and attention to the technical details of surgery and irradiation. The other type of recurrence is a manifestation of a biologically aggressive tumor and represents a first site of metastatic disease. This type of recurrence is similar to the majority of chest wall recurrences after mastectomy.

FIGURE 74.21. Cosmetic outcome after breast-conserving therapy with radiation. A: Excellent cosmetic outcome. The treated breast (*left*) is identical to the untreated breast. B: Fair cosmetic outcome. Significant shrinkage and loss of ptosis is evident in the treated right breast.

FIGURE 74.22. Incision placement for modified radical mastectomy. The incision should include the nipple-areola complex, biopsy scar, and excess skin of the breast.

Mastectomy. The term *mastectomy* describes the removal of all grossly evident breast tissue. If only the breast is removed, the operation is called *total* or *simple mastectomy*. If the breast and most or all of the axillary lymph nodes are removed, the procedure is termed *modified radical mastectomy*. Mastectomy has traditionally been performed through an elliptical incision that encompasses the nipple-areola complex and the biopsy scar, if an open biopsy has been performed, in addition to the excess skin of the breast (Fig. 74.22). If the skin is needed for reconstruction, it can be preserved and exposure obtained through incision rather than excision, a procedure known as *skin-sparing mastectomy*. Skin flaps are raised in the plane between the subcutaneous fat and the underlying breast tissue. To encompass all the breast tissue, the dissection should extend superiorly to the inferior border of the clavicle, medially to the lateral border of the sternum, inferiorly to the superior extent of the rectus sheath, and laterally to the latissimus dorsi. The fascia overlying the pectoralis major is the deep margin of resection, but it can be preserved when needed to facilitate reconstruction.

Mastectomy is an extremely safe operation. A review of the Surveillance, Epidemiology, and End Results (SEER) from the National Center for Health Statistics data for 10,056 patients treated between 1960 and 1973 reports a 30-day operative mortality of 0.35%.¹⁸⁶ Early postoperative complications include wound infections, which often present as cellulitis and occur in 2% to 14% of cases.¹⁸⁷ Open surgical biopsy before mastectomy (as opposed to a needle biopsy technique) increases the rate of infection. Skin flap necrosis is relatively uncommon today. Factors associated with flap necrosis include vertical incisions, technical error with denuding of the subcutaneous fat from the flap, and closure under tension. Seromas form in 100% of patients and should be considered a side effect and not a complication. Extensive axillary nodal involvement is the strongest predictor of prolonged lymphatic drainage after mastectomy. Seroma formation can be minimized by leaving suction drains in place until their output is less than 30 mL per 24 hours rather than arbitrarily removing them on a predetermined day. Anesthesia of the chest wall is another side effect of mastectomy that patients should be informed of preoperatively.

Mastectomy and Immediate Reconstruction. The techniques of breast reconstruction have evolved dramatically during the past 30 years, and the switch from radical mastectomy to total mastectomy has made immediate reconstruction an option for most women. Tissue expansion followed by removal of the expander and replacement with a permanent implant is the most common form of reconstruction in the United States. The advantage of this technique is that it adds little to the length of surgery or the time of recovery. Disadvantages include the need for a second surgical procedure routinely and the limitations in cosmetic outcome, particularly for women with large or pendulous breasts. These differences, however, are minimized when a bra is worn (Fig. 74.23).

The alternative to implant reconstruction is the use of autologous tissue flaps. Both the transverse rectus abdominis myocutaneous (TRAM) flap and a latissimus dorsi flap have been used for reconstruction. These flaps have the advantage of allowing a more natural look and feel to the breasts than can be achieved with implants (see Fig. 74.18B). The TRAM reconstruction has the added advantage of an abdominoplasty. Both, however, add significant time to the operative procedure, hospitalization, and recovery period, and they may not be suitable for patients with major comorbid conditions. In addition,

FIGURE 74.23. Breast reconstruction with tissue expanders. Although the breasts are not identical, this is not evident when a bra is worn.

in most women the latissimus flap does not provide enough tissue to create a breast mound, and an implant must be added.

Retrospective studies indicate that immediate reconstruction, even after skin-sparing mastectomy, does not increase the risk of local failure.¹⁸⁸ The detection of local failure also does not appear to be altered by the presence of a reconstruction because the majority of chest wall failures occur in the skin or subcutaneous fat. An important issue is the use of immediate reconstruction in patients who will require postoperative RT. The incidence of implant loss and poor cosmetic outcome is clearly increased in patients who undergo postoperative RT, whereas flap necrosis, fibrosis, and shrinkage can occur in TRAM flaps after radiation. As the indications for postoperative RT have expanded (discussed later), the issue of the optimal method and timing of reconstruction has become a subject of great controversy. Good cosmetic outcomes have been reported after irradiation of both implants and tissue flaps. Alternative approaches include the placement of an expander to allow skin preservation at the time of initial surgery,¹⁸⁹ with a decision to continue with the expander and implant, to switch to a flap reconstruction at the completion of oncologic therapy, or to delay reconstruction until after the completion of irradiation.

Management of the Axillary Nodes

Axillary dissection has been a part of the surgical management of breast cancer since the era of Halsted. Initially, axillary dissection was thought to be therapeutic, but came to be regarded as a staging procedure when it became evident that the majority of women with nodal metastases died of breast cancer after receiving local therapy alone. In the 1990s, the increasing use of adjuvant systemic therapy for node-positive and node-negative breast cancer, the more frequent detection of small cancers associated with a low risk for nodal metastases, and an increased awareness of the morbidity of axillary dissection resulted in attempts to identify subgroups of patients who would not benefit from the procedure. In most studies, tumor size was used to identify a low-risk subgroup. Even for tumors smaller than 5 mm, however, the incidence of nodal metastases ranges from 3% to 12%.¹⁸³ For the majority of patients with breast cancer, the axillary nodal status cannot be reliably predicted on the basis of the characteristics of the primary tumor. Today, sentinel node biopsy allows the reliable identification of patients with axillary metastases with a low-morbidity staging procedure.

Sentinel Node Biopsy. A sentinel lymph node (SN) is defined as the first lymph node that receives drainage from a

cancer. The procedure of lymphatic mapping can be performed with Lymphazurin blue dye, colloids labeled with radioactive isotopes (usually technetium), or a combination of the two agents. The SN technique was initially developed and validated in studies from single surgeons or institutions where SN biopsy was followed by axillary dissection.¹⁹⁰

A number of prospective, multi-institutional studies have examined the ability to identify an SN and the accuracy of the SN in predicting the status of the remaining axillary nodes.^{191–194} These are summarized in Table 74.13. These studies indicate that regardless of the technique used, surgeons learning the procedure can identify a SN in approximately 95% of patients, which will predict the status of the remaining axillary nodes in about 90% of cases. It is apparent that SN biopsy can be performed in most patients with breast cancer. The management of the axillary lymph nodes is listed in Table 74.14. A randomized comparison has demonstrated that equal numbers of node-positive women are identified with SN biopsy and axillary dissection.¹⁹⁵ The morbidity of SN biopsy is significantly lower than that of axillary dissection, both 6 months and 2 years postoperatively, and the incidence of lymphedema is significantly lower.¹⁸¹ After SN biopsy alone, isolated axillary recurrence occurs in fewer than 1% of patients, making it the axillary staging procedure of choice for most patients with breast cancer. Sentinel node biopsy also offers the pathologist the opportunity to perform a much more detailed study of the lymph node that is most likely to contain metastases than is possible when an entire axillary specimen containing 15 to 30 nodes is evaluated. With the use of multiple sections or immunohistochemistry, it is possible to identify tumor deposits in approximately 20% of nodes found to be “negative” with routine sectioning and hematoxylin and eosin staining. The prognostic significance of these micrometastases,

TABLE 74.14

APPROACH TO THE AXILLARY NODES

■ FINDING	■ APPROACH
Clinically negative	Sentinel node biopsy
Radiographically suspicious	Ultrasound-guided fine-needle aspiration Axillary dissection if positive Sentinel node biopsy if negative
Clinically suspicious	Fine-needle aspiration (image or hand guided) Follow-up management as for radiographically suspicious

however, is uncertain. Prospective clinical trials performed by the American College of Surgeons Oncology Group and the NSABP will determine whether immunohistochemistry of the SN is a useful way to refine our ability to predict the risk for recurrence.

Axillary Dissection. Axillary dissection is indicated in patients found to have metastatic disease in the SN or those with contraindications to SN biopsy. The extent of axillary dissection has been defined on the basis of the number of nodes removed or their anatomic location. As discussed in the section on anatomy, the axilla is divided into three anatomic levels. Removal of the level I and II nodes accurately identifies metastases in 98% of patients because isolated metastases to level III are uncommon. A level I and II dissection is standard practice, with the removal of level III being reserved for patients with evidence of gross nodal involvement. Isolated axillary recurrence after a level I and II dissection is uncommon, occurring in fewer than 3% of patients undergoing BCT. With random node removal, a clear relationship is noted between the number of nodes removed and the incidence of axillary failure.

It has become increasingly apparent that axillary dissection is accompanied by significant morbidity. Major complications, such as injury to the axillary vein and motor nerves of the axilla, are rare, but numbness in the distribution of the intercostobrachial nerve occurs in 70% to 80% of patients unless the nerve is preserved, and 20% to 30% of patients have pain and weakness 1 year after surgery.¹⁹⁵ The risk of lymphedema after axillary surgery persists for the patient's lifetime, and the frequency of lymphedema increases as the time from surgery increases. In a review of reports published in the 1990s,¹⁹⁶ the incidence of lymphedema was found to range from 6% to 30%. The incidence of lymphedema is related to the extent of axillary dissection, being higher when level III is removed than when lesser dissections are performed. The radiation of an axillary field after surgical dissection significantly increases the risk for lymphedema. Beyond these two treatment-related factors, there is little agreement regarding which patient characteristics are associated with an increased risk for lymphedema.

Postmastectomy Radiotherapy

The reasons for irradiating the chest wall and draining lymph node basins after mastectomy are twofold: first, to reduce the risk for locoregional recurrence of tumor, and second, to improve survival by eradicating residual locoregional disease that may be resistant to systemic therapy. The risk for local failure after mastectomy is significant and is clearly related to the presence of axillary node metastases, and large (>5 cm) tumor size. Reported locoregional recurrence rates in randomized trials of mastectomy alone range from 4% to 26%.¹⁹⁷ In patients with negative axillary nodes, local failure rates are usually less than 4%. An overview analysis of 40 trials (19,582 women) of RT after both mastectomy and BCT demonstrated that RT reduces the risk for local recurrence by approximately two thirds.¹⁹⁸ A much smaller decrease in breast cancer mortality was also observed (proportional reduction: 9%) but, in older studies, was offset by a significant increase in late cardiac mortality in women who underwent radiation for left-sided cancers.

Recent studies have examined the use of RT in patients receiving adjuvant systemic therapy and have reported an improvement in survival with the addition of RT in node-positive women. The Early Breast Cancer Trialists' Collaborative Group Overview¹⁵⁵ demonstrated a survival benefit for RT when used for patients with both one to three, and four or more, involved axillary nodes. However, the extent of the axillary dissections performed in some of these studies was

limited, resulting in a relatively high rate of axillary recurrences than is observed in many studies in the United States. For this reason, debate continues on the need for RT in women with breast cancers less than 5 cm in size and involvement of one to three axillary nodes. In patients with involvement of four or more nodes, RT is recommended routinely, regardless of tumor size.

PROGNOSTIC FACTORS

The clinical course of breast cancer varies from patient to patient. Prognostic factors can be used to predict the natural history of a tumor, usually in terms of disease-free or overall survival. Prognostic factors must be distinguished from predictive factors, which are associated with response to a particular therapy. Clinically, prognostic factors are used to determine which patients have such a favorable outcome after local therapy that adjuvant systemic therapy is not warranted. Although multiple prognostic factors have been described, those in standard use today include axillary lymph node status, tumor size, histologic subtype (discussed in the section on pathology), nuclear or histologic grade, and ER and PR status. Measurements of proliferation, such as S-phase fraction or Ki67, are more controversial but are used in many institutions. Newer factors under study include cyclins, growth factor receptors, plasminogen activators, and inhibitors and markers of cell death (e.g., BCL-2).

The presence of metastases to the axillary nodes is the single most important prognostic factor in breast cancer. Although clinical studies usually divide patients into groups with negative nodes, one to three positive nodes, and four or more positive nodes, the number of involved nodes indicates the prognosis as a continuous variable. Because patients with node-positive disease are uniformly recognized as requiring adjuvant systemic therapy, most studies have concentrated on prognostic factors in patients with node-negative disease. Tumor size is another strong predictor of outcome.^{199,200} Only 10% or less of patients with tumors 1 cm or less in size and negative axillary lymph nodes experience recurrence during long-term follow-up.¹⁹⁹

Tumor grade has also been shown to predict outcome in breast cancer. However, the availability of multiple grading systems, poor reproducibility among different observers unless specific guidelines are provided, and the failure in the past of many pathologists to include a grade on the pathology report have limited its utility as a prognostic factor. Hormone receptor (ER and PR) status has long been recognized as a predictive factor for response to endocrine manipulations (e.g., tamoxifen or oophorectomy). In addition, studies have demonstrated that ER and PR are prognostic factors that are associated with increases in disease-free survival of about 10% at 5 years.²⁰¹ ER and PR levels are strongly correlated with histologic grade and patient age, and inversely correlated with measures of proliferation.

Although many prognostic factors have been examined, relatively few have shown clinical utility. In addition, most studies of prognostic factors have examined one or two factors, making it difficult to predict the outcome of patients with a mixture of favorable and unfavorable prognostic features. Drawing on information from the SEER database, the results of individual clinical trials, and published literature, Ravdin et al.²⁰² developed a novel computerized system called Adjuvant! that projects patient outcomes at 10 years based on a combination of classic clinicopathologic features. Adjuvant! is an evidence-based tool to facilitate clinical decisions based on the risk of recurrence and the potential benefit from adjuvant therapies. This prognostic tool has been independently validated, and observed outcomes were within 2% for most demographic, pathologic, and treatment-defined subgroups.²⁰³

The advent of genomic technology for the analysis of human tumor samples has added an additional source of information to aid in determining prognosis and clinical decisions. The intrinsic subsets of breast cancer, as first described by Perou et al.¹⁶⁴ (HER2, luminal A, luminal B, and basal-like), are associated with different relapse-free and overall survival rates, with those in the luminal subgroup having the best prognosis and those in the basal cell group having a significantly worse prognosis.^{165,166} Efforts to define more limited sets of genes for prognostic purposes include a 70-gene expression profile first described by van de Vijver et al. in 2002.²⁰⁴ Commonly referred to as the Amsterdam signature, this expression profile was used to classify 295 patients with breast cancer into a good- or poor-prognosis groups, on the basis of distant relapse and overall survival. Interestingly, women with node-positive and node-negative disease were evenly distributed between the two groups, whereas other recognized poor-prognostic factors (e.g., ER negativity, high histologic grade) were clustered in the poor-prognosis group. The 10-year disease-free survival was 94.5% in the good-prognosis group and 50.6% in the poor-prognosis group. This genomic assay, which requires fresh frozen tumor samples, is now commercially available as MammaPrint and is undergoing clinical validation as part of a multicenter trial.

Another gene-based approach is a 21-gene assay using reverse transcription polymerase chain reaction (RT-PCR) on RNA isolated from paraffin-embedded breast tumors (Oncotype DX). This assay provides individualized risk estimates based on measurements of 16 cancer-related genes and five reference genes. It was originally developed for use in ER-positive, node-negative patients by retrospective analysis of available tumor tissue from 447 patients treated with tamoxifen \pm chemotherapy in three clinical trials, and the risk of recurrence at 10 years was quantified (recurrence score [RS]).²⁰⁵ Independent validation was performed on 668 stage I or II, node-negative, hormone receptor-positive patients treated with tamoxifen from the NSABP B-14 trial.²⁰⁶ In the validation study, the RS was superior to age, tumor size, and grade in predicting prognosis, and when subdivided into low-risk (RS <18), intermediate-risk (RS 18 to 30), and high-risk (RS >31) groups, the 10-year disease-free survival was 69% for the high-risk group and 93% for the low-risk group. Further analysis of patients from the NSABP B-20 trial demonstrated that patients in the high-risk group experienced a significant benefit from the addition of chemotherapy to tamoxifen, whereas those in the

intermediate- and low-risk groups derived little to no benefit from chemotherapy. This 21-gene expression assay has been accepted as a clinical practice tool for appropriately selected patients; however, optimal therapy for patients in the intermediate-risk group remains unclear, and this question is being tested in a prospective trial (TAILORx) where Oncotype DX will be used to select hormone receptor-positive, node-negative patients with an intermediate RS for randomization to hormonal therapy or combined hormonal therapy and chemotherapy. Additional studies have shown that the recurrence score is also prognostic and predictive of the benefit of chemotherapy in node-positive, ER-positive patients.

ADJUVANT SYSTEMIC THERAPY

Adjuvant therapy is defined as the use of cytotoxic chemotherapy or endocrine therapy after the local treatment of breast cancer to eliminate clinically occult micrometastases, thereby preventing recurrence and increasing survival. Initially, adjuvant systemic therapy trials were carried out in patients with node-positive disease, who are at the highest risk of relapse. Subsequently, the recognition that breast cancer death occurs in up to 40% of patients with node-negative breast cancer led to trials of systemic treatment in that group.

The Early Breast Cancer Trialists Collaborative Group has conducted meta-analyses of the major prospective, randomized trials of chemotherapy, with the most recent analysis published in 2005 (Table 74.15).²⁰⁷ After 15 years of follow-up, this analysis confirmed that adjuvant chemotherapy reduces the proportional risk of death equally in patients with node-positive and node-negative disease. There is a small benefit for anthracycline-based treatment (e.g., doxorubicin) versus Cytoxan, methotrexate, and fluorouracil. The benefit of chemotherapy was greatest in younger women, reducing the odds of death by 29% in those under 40 and by 9% in those ages 60 to 69. A separate meta-analysis of 16 randomized trials comparing taxane (paclitaxel or docetaxel)-containing regimens to non-taxane-containing regimens in the adjuvant setting for women with node-positive and high-risk node-negative disease demonstrates a small added benefit with the use of taxanes for this group of patients.²⁰⁸ The next Oxford Overview by the Early Breast Cancer Trialists Collaborative Group will also examine this question.

Modified from Stearns V, Davidson NE. Adjuvant chemotherapy and chemoendocrine therapy. In: Harris JR, Lippman ME, Morrow M, et al., eds. *Diseases of the Breast*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:895.

The advent of trastuzumab (Herceptin) therapy in the adjuvant management of HER2-positive breast cancer in 2005 was a major breakthrough in the application of targeted therapy to breast cancer. Herceptin is a recombinant humanized monoclonal antibody specific for the external region of the HER2 transmembrane tyrosine kinase. To date, results from five studies, which have randomized 11,650 women with early-stage HER2-positive breast cancer to trastuzumab- versus non-trastuzumab-based adjuvant chemotherapy, have demonstrated that the addition of trastuzumab results in a significant improvement in both disease-free (50%) and overall survival (33%).^{209–213} The clinical benefit of trastuzumab appears to be limited to tumors with HER2 amplification. Lapatinib, a next-generation tyrosine kinase inhibitor, which reversibly inhibits both the EGFR (HER1) and HER2 kinases, has been approved for use in the metastatic setting. The role of lapatinib in early-stage disease is being explored both in the adjuvant and neoadjuvant settings.

Adjuvant endocrine therapy is standard therapy for both pre- and postmenopausal women with hormone receptor-positive disease. Tamoxifen is a nonsteroidal agent that exhibits site-specific estrogen agonist and antagonist properties.²¹⁴ It was the first drug identified in the class now referred to as SERMs. Tamoxifen acts as an antiestrogen in the breast through competitive blockade of the ER. In bones and lipids, tamoxifen acts as an estrogen agonist, preserving bone density and lowering blood cholesterol. Tamoxifen also acts as an agonist in the uterus, increasing the incidence of endometrial carcinoma (see section on management of the high-risk woman). The most recent Early Breast Cancer Trialists Collaborative Group meta-analysis also included more than 48,000 patients in 56 trials of tamoxifen.²⁰⁷ The use of tamoxifen for 5 years reduces the annual odds of breast cancer recurrence by 41% and the annual odds of death by 34%. Tamoxifen is beneficial in women of all ages, and 5 years of therapy is superior to shorter durations of treatment. These benefits are limited to patients whose tumors express ER, PR, or both.

Tamoxifen was the cornerstone of endocrine therapy for postmenopausal women with hormone receptor-positive disease until the recent reporting of several adjuvant AI trials. AIs function by inhibiting the peripheral conversion of androgens to estrogen, thereby lowering estrogen levels. Adjuvant AIs have been compared to tamoxifen in a number of study designs including sequential strategies²¹⁵ (AI given after 2 to 3 years of tamoxifen), upfront strategies²¹⁶ (AI instead of tamoxifen), and extended strategies²¹⁷ (AI given after 5 years of tamoxifen). All of these strategies have demonstrated significant recurrence-free survival benefits over tamoxifen alone; however, the superiority of any given strategy remains to be determined. One of these agents, anastrozole, was compared with tamoxifen alone or in combination with anastrozole in a randomized trial of more than 9,000 postmenopausal women (ATAC trial).²¹⁶ At 9 years' follow-up, the anastrozole-alone arm showed a 4.8% recurrence-free survival benefit over tamoxifen alone; however, no overall survival benefit has been observed. The tolerability profile of anastrozole is somewhat better than that for tamoxifen, with fewer hot flashes, no endometrial effects, and fewer thromboembolic events. However, arthralgias and myalgias are more commonly reported, and the risk of fracture is increased during the 5 years of treatment.

The overview analysis of randomized trials²⁰⁷ also demonstrates that combined therapy with chemotherapy and tamoxifen is superior to treatment with either agent alone in both premenopausal and postmenopausal women. In postmenopausal women, however, the benefit from the addition of chemotherapy is modest and must be weighed against the toxicity of the treatment in the context of the patient's overall health. General guidelines for the use of adjuvant therapy are shown in Table 74.16, but final treatment decisions

TABLE 74.16**TREATMENT****RECOMMENDATIONS FOR ADJUVANT THERAPY**

■ PATIENT GROUP	■ RECOMMENDED TREATMENT
NODE NEGATIVE, LOW RISK	
Tumor <1 cm	No treatment or endocrine therapy if ER+
Special histologic types 1–2 cm, grade 1, ER+	
NODE NEGATIVE, HIGHER RISK	
ER+	Endocrine therapy OR chemotherapy + endocrine therapy
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy
NODE POSITIVE	
ER+	
Premenopausal	Chemotherapy + endocrine therapy
Postmenopausal	Chemotherapy + endocrine therapy OR endocrine therapy alone
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy
ER+, estrogen receptor positive; ER–, estrogen receptor negative.	

are influenced by the individual attitudes of patients toward possibly small benefits and treatment toxicities. The Oncotype DX assay to predict benefit from therapy is being increasingly used in clinical practice for node-negative, hormone receptor-positive tumors (see discussion under prognostic factors).

SPECIAL PROBLEMS

Breast Cancer in the Elderly

Approximately 50% of breast cancers in the United States are diagnosed in women age 65 and older. Therapy in the elderly should be based on physiologic, not chronologic, age. Mastectomy can be performed safely in the majority of older women, regardless of age, albeit with a slightly higher mortality (0.39% for all ages, and 0.9% for the subgroup of women age 75 and older).¹⁸⁶ Mastectomy is an excellent means of obtaining local control and may minimize outpatient visits, but many older women prefer BCT if offered this option. This is clearly a lesser operative procedure than a mastectomy, and several studies²¹⁸ suggest that local failure rates after BCT with RT are lower in women over age 65 than in their younger counterparts. Radiotherapy is generally well tolerated by older women, but daily visits for RT may be difficult for the elderly patient with limited mobility. In elderly women with tumors under 2 cm in size, the benefit of RT may be marginal, and treatment with wide excision of the tumor and endocrine therapy is an option.²¹⁹ When omission of breast irradiation in the treatment of an elderly patient with larger tumors is considered, it is useful to remember that the majority of local failures occur in the first 6 postoperative years. Sentinel node

biopsy is a low-morbidity staging technique that is particularly well suited to older women. However, if nodal status will not change the recommendation for systemic therapy (e.g., an ER-positive patient not a candidate for chemotherapy), then the routine performance of sentinel node biopsy adds little to patient management.

In the elderly woman with significant comorbid conditions, tamoxifen has been studied as an alternative to conventional surgical treatment. In a review of seven randomized trials, including more than 1,500 women 70 years of age or older, there was no survival advantage for surgical therapy.²²⁰ Although wide resection with free surgical margins was not uniformly required in these studies, significant improvements in local control were noted in the surgically treated woman. The aromatase inhibitor letrozole has been compared with tamoxifen in a randomized trial of neoadjuvant therapy, with letrozole producing a superior local response. Response rates to primary endocrine therapy are high, but 12 months or more are often needed to achieve the best response. With long-term follow-up, the risk for disease progression may be significant. Because surgical treatment is well tolerated by the majority of older women, there is no reason to routinely substitute primary endocrine therapy. For the elderly woman with a limited life span who is a poor operative risk, however, endocrine therapy represents a viable alternative as a primary therapy.

Breast Cancer in Pregnancy

Breast cancer occurring during pregnancy is relatively uncommon when all cases of breast cancer are considered. If only patients with breast cancer in their childbearing years are evaluated, 7% to 14% are found to be pregnant at diagnosis.²²¹ If pregnant women are used as a denominator, approximately 2.2 breast cancers per 10,000 pregnancies can be anticipated.

The clinical presentation of breast cancer during pregnancy is the same as in the nonpregnant patient, and a palpable mass is the most common symptom. Mammography is not particularly helpful in the evaluation of breast masses in pregnant women because of the increased density of the breast. Ultrasonography is often useful in distinguishing a true mass from the normal nodularity of pregnancy, but ultimately the decision about the need for biopsy should be made on the basis of the physical examination. Delay in the diagnosis of breast cancer during pregnancy remains a major problem, and most of this delay is physician induced. Core needle biopsy or breast biopsy under local anesthesia is safe at any time during pregnancy and should be performed for any suspicious mass.

The options for the local treatment of breast cancer during pregnancy are limited for the woman who wishes to continue her pregnancy. The use of irradiation during any trimester of pregnancy is contraindicated because of the inability to shield the fetus from internal radiation scatter. If breast cancer is diagnosed in the third trimester, lumpectomy can be performed and radiation delayed until after delivery. The effect of longer delays in radiation to allow breast preservation is unknown and may be detrimental. Immediate reconstruction with tissue flaps is also contraindicated during pregnancy because of the risk to the fetus of a more prolonged anesthesia and increased blood loss, in addition to the inability to obtain symmetry with the postpartum breast. Thus, mastectomy remains the mainstay of the surgical therapy of breast cancer during pregnancy. The safety of radio-colloids and blue dyes used for SN biopsy during pregnancy is unclear,²²² so axillary staging is done with an axillary dissection, although newer modeling studies suggest that the dose of radioactivity used for lymphatic mapping is safe during pregnancy. Therapeutic abortion does not appear to play a role in the treatment of nonmetastatic breast carcinoma. A

number of small, nonrandomized studies have failed to show a survival advantage associated with termination of pregnancy. Some patients may opt to terminate a pregnancy because of concerns about the long-term prognosis or the risk for fetal damage, but patients should not be advised that this is of therapeutic benefit.

Breast cancer during pregnancy is often thought to be a particularly aggressive disease with a poor prognosis. Much of the poor prognosis, however, seems to be secondary to advanced disease at the time of diagnosis. These women are generally too young to undergo regular mammographic screening before pregnancy, and even in recent series, more than 60% of patients with pregnancy-associated breast cancer had positive axillary nodes. After correction for age and tumor stage, some studies suggest that survival in women treated during pregnancy is similar to that of nonpregnant patients. Population-based studies in Denmark, Sweden, and the United States indicate, however, that survival decreases significantly when breast cancer is diagnosed during pregnancy or shortly thereafter.^{223–225}

Chemotherapy can be given to the pregnant patient with breast cancer but is generally delayed until after the first trimester. Fetal malformation occurs in approximately 20% of patients treated during the first trimester, and this risk falls to about 2% for exposure in the second and third trimesters. Some series, however, have reported low birth weight in as many of 40% of infants exposed to chemotherapy during pregnancy, and the long-term effects of chemotherapy exposure on growth, development, and cancer risk are largely unknown.²²⁶ The decision to treat any woman with chemotherapy during pregnancy depends on her risk for relapse and the woman's desire for treatment after a thorough discussion of the risks and benefits, and these decisions must be resolved on a case-by-case basis. When breast cancer is diagnosed in the third trimester, chemotherapy can usually be delayed until fetal maturity, when delivery can be induced. The effects of longer delays on the efficacy of chemotherapy are unknown. Tamoxifen is contraindicated in pregnant women, and women undergoing chemotherapy or endocrine therapy should not breastfeed.

Male Breast Cancer

Cancer of the male breast is an uncommon disease. Risk factors include Klinefelter syndrome, a family history of breast cancer, mutations of the *BRCA2* gene, hepatic disorders, and radiation exposure. With the exception of the gynecomastia in Klinefelter disease, there is no clear association with gynecomastia. The mean age of patients at presentation with male breast cancer is approximately 10 years older than that of women with the disease.²²⁷ The typical presentation is a mass beneath the nipple-areola complex, with retraction or ulceration of the nipple; nipple discharge is less frequent. Approximately 80% of male breast cancers are hormone receptor positive.

The most common local treatment for male breast carcinoma is mastectomy. Radical mastectomy is no longer the standard therapy, and when the tumor is not fixed to the pectoral muscle, a total mastectomy can be performed. With limited muscle involvement, the portion of the pectoralis adherent to the tumor can be excised. When extensive pectoral muscle invasion is present, radical mastectomy may be necessary, although preoperative chemotherapy, as in female breast cancer, is also an option. BCT for male breast carcinoma is rarely feasible because of the small size of the breast and the central location of most tumors. Several small studies in men with breast cancer support the use of SN biopsy if the axilla is clinically negative; axillary dissection is indicated if nodal metastases are documented preoperatively.²²⁸

The survival rate of men with breast cancer is similar to that in women with disease of the same stage,²²⁹ and axillary

nodal status is the major predictor of outcome. The benefit of adjuvant systemic therapy in male breast cancer has not been evaluated in randomized clinical trials, but the natural history and response to therapy of metastatic breast carcinoma in men is similar to that in postmenopausal women, leading to similar practice in the adjuvant setting. Because most male breast cancers contain hormone receptors, the largest adjuvant experience has been gained with hormonal therapy. The administration of tamoxifen to men with stage II or III disease resulted in a 55% 5-year survival, versus 28% in historical controls who received no systemic treatment.²³⁰ Tamoxifen, however, may not be as well tolerated in men as in women, and frequently causes decreased libido. The use of aromatase inhibitors in men with breast cancer is being explored, but an AI alone is not appropriate. Only 80% of circulating estrogen in men is derived from peripheral aromatization, and inhibition of aromatization activates the hypothalamic-pituitary axis negative feedback loop, resulting in increased androgen production.²³¹ Therefore, complete estrogen suppression is not achieved with an AI alone, and tamoxifen remains the mainstay of endocrine therapy in men. In general, the use of adjuvant systemic therapy should be based on prognosis and hormone receptor status, and the guidelines for postmenopausal women should be followed. Orchiectomy is an option as second-line hormonal manipulation in men with metastatic disease, with an 80% response rate to castration, in men with receptor-positive cancer.²³²

Occult Primary Tumor Presenting with Nodal Metastases

Breast cancer presenting as metastatic disease in the axillary nodes with no evident tumor in the breast is uncommon, accounting for fewer than 1% of cases in most large series. Metastatic adenocarcinoma in axillary nodes may be secondary to a variety of primary cancers, but in women, breast cancer is by far the most common type. In the patient without historical or clinical evidence suggesting a primary tumor at another site, the radiologic evaluation should be confined to breast imaging and a chest radiograph. Examination of the nodal tissue for hormone receptors and HER2 overexpression helps to confirm a breast primary tumor if the tissue is hormone receptor or HER2 positive, but the breast cannot be excluded as the site of the primary tumor if the nodal tissue does not contain receptors.

Magnetic resonance imaging is often successful in identifying a primary tumor when mammography and ultrasound are normal. Buchanan et al.²³³ identified a primary tumor in 26 of 55 (47%) patients presenting with axillary adenopathy in the absence of distant disease. In patients presenting with axillary adenopathy and synchronous distant disease, MRI identified the primary tumor in 12 of 14 (86%) patients. Identification of a primary tumor greatly facilitates BCT and, in this circumstance, the patient can be managed in the same way as any stage II cancer.

Historically, when a primary tumor has not been identified, most women with axillary node metastases secondary to a presumed breast cancer have been treated with mastectomy, and a breast carcinoma was identified during the pathologic evaluation in approximately 65% of these cases. In older reports, the size of the occult tumors varied widely, with lesions as large as 6 cm reported. In more recent studies of patients evaluated with modern imaging techniques, large tumors are uncommon, and this has stimulated interest in breast preservation even when the tumor cannot be identified. In the largest reported series from the Institute Curie, 54 patients received whole breast irradiation (median dose 59 Gy). The 5- and 10-year rates of ipsilateral breast recurrence were 7.5% and 20%, respectively, supporting the idea that this is a reasonable

approach.²³⁴ In contrast, studies in which the breast was observed without treatment indicate that evident breast cancers develop in close to 50% of patients within 5 years.^{235,236} Additional positive axillary nodes are frequent in this circumstance, so axillary dissection should be performed regardless of the method that is selected for managing the breast. The prognosis for patients with occult primary tumors is similar to that for patients with clinically evident tumors matched for the number of involved nodes, and adjuvant systemic therapy should be administered according to established guidelines for patients with node-positive disease.

Locally Recurrent Breast Carcinoma

Local recurrence in the breast after BCT may be a consequence of inappropriate patient selection, poor surgical or radiotherapeutic technique, or tumor biology. When errors in technique and selection are excluded, local recurrence in the first 2 postoperative years is uncommon. From years 2 to 6, local recurrence develops at a constant rate, usually at or adjacent to the site of the original tumor. After year 6, most local recurrence develops in other quadrants of the breast, which suggests that these are new primary tumors rather than true local failures. This idea is supported by the observation that the risk for late recurrence in other quadrants of the breast, approximately 1% annually, is equal to the risk for development of a new contralateral breast carcinoma.

Most recurrences are in the breast parenchyma, with approximately 5% to 10% developing in the skin as diffuse inflammatory-type recurrences.²³⁷ Before further local therapy, an evaluation to exclude metastatic disease is appropriate because concomitant distant metastases are present in 5% to 10% of cases. In the absence of distant metastases, complete mastectomy has been the mainstay of therapy. Five-year relapse-free survival rates range from 60% to 79% after the procedure, and further chest wall recurrences are uncommon. Small experiences with further attempts at breast preservation by using excision alone or repeated irradiation of small areas of the breast after surgical excision have been reported, but larger numbers of patients and longer follow-up periods are needed to determine the role of these therapies. The role of adjuvant systemic therapy in the management of recurrence is not well defined. In patients who have not received prior systemic therapy, we use the same criteria for treatment that are used for patients with newly diagnosed cancer. Treatment decisions for patients who received adjuvant systemic therapy at the time of diagnosis are made on a case-by-case basis.

Local recurrence after mastectomy develops in a different time frame, and the predictors and outcome are different than for local recurrence after BCT. Approximately 75% of cases of local recurrence after mastectomy develop in the first 3 postoperative years, and about half of these are associated with the development of distant metastases at the time of local recurrence or within a few years. The number of axillary nodes containing metastasis is the best predictor of the risk for chest wall recurrence.

An evaluation for distant metastases is an essential part of the workup of local recurrence after mastectomy. Small, localized recurrences are usually excised, but even with complete excision, RT should be administered to the chest wall because it is safe to assume that all the lymphatics are seeded with tumor. The supraclavicular space is usually included in the radiation field because these nodes are the second most frequent site of locoregional recurrence. The value of treating the axillary space and the internal mammary nodes is uncertain because clinical recurrence at these sites is uncommon. The value of additional systemic therapy for patients who have received postoperative adjuvant therapy is also uncertain.

Paget Disease of the Nipple

Paget disease of the nipple comprises 1% to 3% of all breast cancers. It is characterized by eczematoid changes of the nipple (Fig. 74.24), frequently present for 6 months or more before diagnosis, and often accompanied by itching, erythema, and nipple discharge. Paget disease is diagnosed histologically by the presence of large cells with pale cytoplasm and prominent nucleoli (Paget cells) involving the epidermis of the nipple. In 1874, Sir James Paget reported that this condition is invariably followed by cancer of the breast, usually within 1 year of diagnosis.²³⁸ It is now recognized that the majority of women with Paget disease have an associated infiltrating or intraductal carcinoma, which may manifest as a palpable mass or as mammographic findings.

Paget disease has traditionally been treated with mastectomy. The reasons include the need to sacrifice the nipple–areola complex, the fact that subareolar ducts may be diffusely involved with tumor, and the observation that carcinoma may be found at a considerable distance from the nipple. A limited experience with breast-conserving procedures in the management of Paget disease has been described. Because Paget disease is a noninvasive carcinoma involving the nipple that usually is associated with intraductal or invasive carcinoma in the underlying breast parenchyma, the appropriateness of BCT is determined by the extent of the underlying involvement. A detailed mammographic evaluation (including magnification views of the subareolar region) and histologic evaluation with margin assessment are essential components of this assessment. Further evaluation with breast MRI may be considered in patients with Paget disease and a negative mammographic evaluation.²³⁹ For patients with evidence of diffuse involvement or disease at a distance from the nipple, mastectomy remains the standard therapy. In patients with disease localized to the subareolar area or the nipple–areola complex, BCT can be considered. This treatment requires removal of the entire nipple–areola complex and some of the underlying ductal region. In carefully selected patients, local failure rates with this approach appear to be similar to those reported for other breast carcinomas. Radiotherapy has been increasingly employed as part of BCT for Paget disease, but no randomized trials have been performed because of the rarity of the condition.²⁴⁰ The prognosis in Paget disease is related to the stage of the disease and appears to be similar to that of women with other types of breast carcinoma. If invasive breast cancer is found, adjuvant systemic therapy should be administered according to the same guidelines used for other patients with invasive cancer.

FIGURE 74.24. Paget disease of the nipple. Depigmentation and desquamation of the nipple and areola are evident.

Phyllodes Tumor

The term *phyllodes tumor* denotes a group of lesions of varying malignant potential, ranging from completely benign tumors to fully malignant sarcomas. (The previous name, *cystosarcoma phyllodes*, is now reserved for fully malignant lesions.) A palpable mass is the most common clinical presentation, and rapid growth is often reported. On examination, phyllodes tumors are smooth, rounded, multinodular lesions that may be indistinguishable from fibroadenomas. Skin ulceration can occur with very large tumors, but this is usually caused by pressure necrosis rather than invasion of the skin by malignant cells (see Fig. 74.5). Histologically, phyllodes tumor, like fibroadenoma, is composed of epithelial elements and a connective tissue stroma.

Phyllodes tumors are classified as benign, borderline, or malignant, based on the nature of the tumor margins (pushing or infiltrative) and the presence of cellular atypia, mitotic activity, and overgrowth in the stroma. Which of these criteria is most important is a matter of disagreement, although most experts favor stromal overgrowth. The percentage of phyllodes tumors classified as malignant ranges from 23% to 50%.^{241,242} Axillary metastases are reported in fewer than 5% of cases but are a poor prognostic sign when present. Metastases more commonly follow the pattern observed with sarcomas (with the lung as the most common site) and histologically resemble sarcomas. Approximately 20% of benign and malignant phyllodes tumors recur locally if excised with no margin or a margin of a few millimeters of normal breast tissue. Barrio et al.²⁴³ reported that in addition to positive margins, fibroproliferation in the surrounding breast tissue and necrosis were associated with a marked increase in local recurrence rates. A wide excision with a 1- to 2-cm margin of normal breast tissue is appropriate therapy for benign and borderline phyllodes tumors unless they are so large that this is not cosmetically feasible. In the past, many authors advocated mastectomy for the management of malignant phyllodes tumors. Because phyllodes tumors are not multicentric, there is no clear-cut biologic rationale for mastectomy, and the successful treatment of malignant phyllodes tumors with wide excision has been reported.²⁴⁴ The use of systemic therapy for malignant phyllodes tumors is based on the guidelines for treating sarcomas.

OTHER CANCERS IN THE BREAST

Sarcomas, lymphomas, and melanomas may all present as breast masses and are generally managed as recommended when they develop in other sites. Angiosarcoma is reported to involve the breast more frequently than other sites in the body. The tumors frequently grow rapidly and may be associated with a bluish discoloration of the skin. Bilateral disease is not uncommon. Angiosarcoma has traditionally been treated with mastectomy to clear margins. Axillary metastases are rare, and axillary dissection is not routinely indicated. The prognosis appears to be related to the grade of the lesion. No advantage has been proved for adjuvant RT or chemotherapy. Other sarcomas occur infrequently in the breast. Surgery is the primary therapy, and the decision to perform mastectomy or wide local excision is based on tumor size.

Melanoma arising from the skin of the breast is a more frequent finding in men than women. The diagnosis, treatment, and prognosis of melanoma arising in the breast are the same as for melanoma arising in other parts of the body. Mastectomy is not necessary for treatment of this lesion.

Primary breast lymphomas are rare and account for fewer than 1% of breast malignancies. They are believed to arise from intramammary lymph nodes or periductal and

perilobular lymphoid tissue. Bilateral disease is present in as many as 25% of patients. The diagnosis is usually made only after a biopsy, as neither the clinical nor the mammographic appearance of these lesions is diagnostic. Once the diagnosis of lymphoma is established, treatment is with chemotherapy or RT, or both, according to the disease stage and histologic subtype.

LOCALLY ADVANCED BREAST CANCER

13 The designation of *locally advanced breast cancer* includes T3 and T4 tumors, those with extensive regional nodal involvement (N2 or N3), and inflammatory breast cancer (Fig. 74.25).

Historical studies have demonstrated that for inflammatory carcinoma and tumors with evidence of skin involvement, chest wall fixation, or extensive axillary nodal disease, initial surgical therapy is associated with a high rate of locoregional recurrence and very poor 5-year survival, with treatment failure usually occurring within 2 years of diagnosis.²⁴⁵ For this reason, locally advanced breast cancer is now approached with a combination of chemotherapy, surgery, and RT. Anthracycline-based neoadjuvant chemotherapy results in partial (50% reduction in primary tumor volume) or complete clinical response (no clinically detectable residual tumor) in 60% to 80% of patients.²⁴⁶ Response rates are further increased by the addition of taxanes to the neoadjuvant protocol, with an increase in clinical complete response (80%–95%), and an increase in pathologic complete response (no residual invasive tumor present on pathologic examination) from 15% to 31%.²⁴⁷ Newer studies also suggest that the addition of Herceptin in the neoadjuvant setting for HER2-positive tumors may further increase the pathologic complete response rate.²⁴⁸ Women who experience a pathologic complete response have significantly better long-term survival than those who do not.²⁴⁹ Although induction chemotherapy is effective in reducing tumor burden and facilitates surgical therapy, no survival advantage has been demonstrated for the use of preoperative, as opposed to postoperative, chemotherapy in randomized trials.

For patients with stage IIIB carcinoma, induction chemotherapy is the standard initial approach. All planned chemotherapy is generally given preoperatively followed by

surgery. Depending on the pretreatment stage and extent of residual tumor, chest wall RT may be indicated to reduce the risk of local recurrence. For the patient with stage IIIA carcinoma that is operable by traditional criteria, the initial therapy can be surgery or chemotherapy. If the patient desires breast preservation, chemotherapy can shrink the tumor sufficiently to allow this in some women. If not, mastectomy can be performed, with chemotherapy and RT given postoperatively in the traditional sequence.²⁵⁰ Women with hormone receptor-positive disease should receive endocrine therapy. Inflammatory breast cancer is a special subtype of locally advanced breast cancer that is characterized by erythema, edema, and peau d'orange, and by diffuse thickening of the breast tissue. This appearance is caused by obstruction of the dermal lymphatics with tumor cells. Inflammatory cancer is always treated with chemotherapy as the initial approach. If all inflammatory skin changes resolve, mastectomy is performed. Radiation to the chest wall is also part of therapy. With modern combined-modality therapy, locoregional control can be maintained in 80% of patients with locally advanced and inflammatory cancer, and 5-year survival rates of 50% to 80% have been reported.^{247,249–251} However, 50% of patients eventually die of metastatic disease, which underscores the need for further research in this area.

CHAPTER 75 ■ THYROID GLAND

BARBRA S. MILLER AND PAUL G. GAUGER

KEY POINTS

- 1 Thyroid follicular tissue in the carotid sheath or the lateral compartments of the neck represents a regional nodal metastasis of an occult thyroid cancer until proven otherwise.
- 2 The tubercle of Zuckerkandl is an anatomic feature of the thyroid that helps facilitate identification of the recurrent laryngeal nerve and the superior parathyroid gland.
- 3 Ultrasound is the imaging procedure of choice for nodular thyroid disease, and surgeon-performed ultrasound helps facilitate operative planning.
- 4 Additional thyroid resection or adjuvant treatment with radioiodine is seldom required for an incidental papillary microcarcinoma found in the surgical specimen.
- 5 Complete investigation of a follicular/indeterminate lesion by fine-needle aspiration currently requires thyroid resection to differentiate a follicular adenoma from a follicular carcinoma based on the presence of capsular or vascular invasion.
- 6 Genotype/phenotype correlation using the specific RET proto-oncogene mutation identified in each patient/family can help determine the appropriate age for prophylactic thyroidectomy in patients with hereditary medullary thyroid carcinoma.
- 7 Extranodal lymphoma of the thyroid or anaplastic thyroid cancer should be considered in the hypothyroid patient who experiences rapid growth of the thyroid.
- 8 Advantages of total thyroidectomy over thyroid lobectomy for differentiated thyroid carcinoma include (a) removal of multifocal intrathyroidal tumors; (b) facilitation of radioiodine imaging and ablation for residual, regional, or metastatic disease; and (c) use of serum thyroglobulin as a sensitive marker of persistent or recurrent disease.
- 9 Routine prophylactic lymph node dissection of the central compartment (level VI) in patients with known papillary thyroid cancer may decrease postoperative thyroglobulin levels and prevent the need for future reoperation in the same compartment.

Excellent patient outcomes for surgical treatment of thyroid disorders are obtainable only by a thorough understanding of embryology, anatomy, physiology, and relevant pharmacology. Delicate and deliberate surgical technique and careful attention to detail are necessary to prevent common complications of thyroid resections.

EMBRYOLOGY AND SURGICAL IMPLICATIONS

Developmental Embryology

As the first endocrine gland to develop, the thyroid is mostly derived of endoderm from the ventral embryologic digestive tract. A midline diverticulum arises in the area of the foramen cecum at the base of the tongue at approximately 4 weeks of gestation. The tissue descends as the median thyroid component, which ultimately becomes the isthmus and the majority of each lateral lobe. The foramen cecum ruptures and resorbs during week 6 of gestational age, leaving behind a regressive fibrous tract, which becomes the thyroglossal duct tract (including the portion associated with the central hyoid bone). The distal end associated with the isthmus persists as a recognizable pyramidal lobe in about 30% to 50% of individuals. The lateral thyroid component develops on each side from the caudal pharyngeal endoderm (with contribution from the fourth and fifth branchial pouches), which arises later in development than the median component.¹ The lateral components become increasingly removed from the pharynx, leaving a tapering connection on each side, which eventually detaches. The residual posterolateral projection from the lateral thyroid component toward the pharynx, when present, is known as the tubercle of Zuckerkandl. Because of its branchial pouch origin, the lateral thyroid component is closely associated with

the superior parathyroid anlage (from the fourth pouch). The lateral components fuse with the posterior portion of the median component on each side, and accompanying C cells (from neural crest origin) migrate into the superolateral portion of the lobes and eventually secrete calcitonin. The unified thyroid begins to differentiate into thyroid follicles between weeks 8 and 11. Basic glandular function begins on a cellular level by the third month of gestation when iodine trapping occurs and thyroid hormones are first manufactured.

Congenital Abnormalities

An uncommon developmental malformation is the lingual thyroid gland. It represents a failure of the median thyroid component to descend from the foramen cecum. The size of a lingual thyroid can often be decreased by using exogenous thyroid hormone to suppress thyroid-stimulating hormone (TSH) or by ¹³¹I ablation. Surgical excision may be required if airway obstruction, obstructive dysphagia, or hemorrhage occurs. Ectopic thyroid tissue can be found in other areas of the central cervical compartment and the mediastinum. These can be sequestered nodules associated with multinodular goiters or they may be embryologic rests of thyroid tissue.² Although the concept of *lateral aberrant thyroid* tissue was originally used to describe the findings of follicular tissue in the carotid sheath or the lateral compartments of the neck, it is now generally agreed that this cannot occur as an embryologic abnormality. If thyroid tissue is found in these areas, it represents a regional nodal metastasis of an occult thyroid cancer. Thyroglossal duct cysts occur in the midline of the neck along the path of descent of the median thyroid component. They may occur from the base of the tongue to the low central neck, although most are located just inferior to the hyoid bone. Although they are often discovered during infancy and childhood, it is not uncommon for them to present

in adulthood—discovered either because of mass effect or infection. When examining the patient, elevation of the mass with protrusion of the tongue is very suggestive of a thyroglossal duct cyst. Resection of a thyroglossal duct cyst involves excision of the entire thyroglossal duct including the cyst. The tract courses through the central portion of the hyoid bone and, for that reason, excision of this segment of bone is critical to prevent recurrence (Sistrunk procedure). The epithelial lining usually contains some thyroid cells and, thus, thyroid carcinomas (usually of papillary type) can arise within thyroglossal duct cysts. Excision of the cyst and the thyroglossal duct may be sufficient for small, limited carcinomas less than 1 cm, but if multifocal elements or regional nodal metastases are present or if the tumor is of sufficient size, total thyroidectomy should be performed to facilitate subsequent ^{131}I scanning and therapy.

ANATOMY AND SURGICAL IMPLICATIONS

A normal thyroid gland (in patients from iodine-sufficient regions) weighs between 15 and 20 g. The upper portion of the isthmus typically crosses at or below the level of the cricoid cartilage. The isthmus itself is approximately 1 to 2 cm in transverse and vertical dimensions and the lower margin of the lobe is normally near the fourth or fifth tracheal ring. The lateral lobes lie adjacent to the thyroid cartilage and cricothyroid muscles as well as the lateral trachea and a portion of the lateral esophagus on each side. The two lobes are roughly conical, approximately 5 cm in craniocaudal and 2 to 3 cm in transverse and anteroposterior dimensions.

Muscular, Fascial, and Airway Relationships

The thyroid lies in the central compartment of the neck bordered by the contents of the carotid sheath on each side. The anterolateral surface is covered by the sternothyroid muscles, which do not completely meet in the midline above the level of the isthmus. Superficial to the sternothyroid muscles are the sternohyoid muscles that meet in the midline raphe marking the most common plane of dissection used to expose the thyroid gland. These muscles are innervated on the inferolateral aspect by the ansa cervicalis (ansa hypoglossi). The thyroid is invested in a thin layer of connective tissue that is an expansion of the pretracheal fascia (often called the “thyroid sheath”). The sheath is not to be confused with the thyroid capsule, which is more integral to the gland itself. The plane defined by this layer is usually easy to develop as the thyroid is mobilized away from surrounding structures. Especially near the superior portion of the thyroid, the sheath defines a coronal plane that, when opened, exposes the potential space between the pharynx/esophagus and the cervical vertebral bodies. The sheath is condensed as the anterior suspensory ligament above the isthmus. The sheath also attaches the posterior surface of the thyroid gland to the tracheal rings. It is condensed posteromedially into the ligament of Berry on each side. The ligament of Berry is a very firm attachment to the trachea near the cricothyroid space, which means that it is often intimately associated with the recurrent laryngeal nerve (RLN) near its insertion. It is in the course of dividing these posterior attachments that the RLN is most vulnerable to iatrogenic injury. The superior parathyroid gland may be found between the sheath and the thyroid capsule, within the sheath, or posterior to the sheath.

Vascular Relationships

The thyroid gland has a very high blood flow index per tissue mass and receives its arterial supply from a paired system of superior thyroid arteries (originating from the external carotid

arteries) and inferior thyroid arteries (originating from the thyrocervical trunks). The superior artery courses along the inferior pharyngeal constrictor muscle group and branches near the tip of the superior pole of the thyroid, usually into at least an anterior and posterior branch. The inferior thyroid artery (ITA) courses upward behind the carotid artery and then crosses medially to serve the thyroid lobe. The ITA has multiple branches that course in a plane between the sheath and the capsule of the gland. The relationship of the ITA to the RLN is an important landmark. There is always an intersection (except in the case of a direct/nonrecurrent laryngeal nerve), but the specific relationship (anterior, posterior, or interdigitated) may be variable. Occasionally, an arteria thyroidea ima arises from the aorta or innominate artery and directly serves the inferior portion of the thyroid gland. Venous drainage is by a widely anastomosing system that condenses into three main trunks. The superior thyroid veins course adjacent to the superior thyroid arteries but empty into the internal jugular vein at the level of the carotid bifurcation. Middle thyroid veins are present in more than half of patients and drain laterally to the internal jugular vein. These veins are divided early in the course of mobilizing the thyroid lobe. In tracing a vessel laterally, if it passes anterior to the carotid artery, it is a middle thyroid vein, whereas if it passes deep to the carotid, it is the ITA. The inferior thyroid veins form nearly all of the vascular connections found at the inferior poles of the thyroid lobes. The number and configuration of these veins can be quite variable, but in general they descend along the course of the thyrothymic tract to drain into the ipsilateral innominate or brachiocephalic veins.

Neurologic Relationships

Two nerves have critical importance during thyroidectomy: the RLN (also known as the inferior laryngeal nerve) and the external branch of the superior laryngeal nerve. The right recurrent laryngeal nerve arises from the vagus at the level of the subclavian artery and passes (recurs) around the posterior aspect of the artery before ascending into the central compartment. The nerve takes an oblique course in the central neck and may be 1 to 2 cm lateral to the trachea low in the central neck before traveling toward its entry into the larynx. The left RLN arises from the vagus nerve as it crosses the aortic arch. It passes inferior and medial to the arch and ascends to the larynx in the tracheoesophageal groove along a course that is typically linear and more vertical. The RLN often lies immediately posterolateral to the ligament of Berry, but it is not infrequent that it can be embedded in the fibrous connections of the ligament itself, especially the anterior branch of the nerve if it bifurcates outside the larynx. Pelizzo et al. have described the tubercle of Zuckerkandl as a constant anatomic landmark to facilitate identification of the recurrent laryngeal nerve during thyroid resection.³ In the standard anatomic relationship, the tubercle of Zuckerkandl lies immediately lateral to and covers the RLN (Fig. 75.1). An uncommon but high-risk anatomic arrangement

FIGURE 75.1. The standard anatomic relationship whereby the recurrent laryngeal nerve (RLN) passes medial to the tubercle of Zuckerkandl before its insertion into the cricothyroid interval.

FIGURE 75.2. The uncommon but high-risk anatomic variation where the recurrent laryngeal nerve (RLN) courses lateral to the tubercle of Zuckerkandl, which is often enlarged. The nerve is encountered much earlier in the dissection required for thyroidectomy and is at risk of being misidentified as a vascular structure.

occurs when the RLN is found lateral to the tubercle of Zuckerkandl (Fig. 75.2). If the surgeon is unaware of this possibility (which may exist when the tubercle has undergone nodular enlargement), the nerve is subject to iatrogenic injury.⁴ The nerve usually bifurcates extralaryngeally but often at a point less than 0.5 cm from the cricoid cartilage. Up to 58% of recurrent laryngeal nerves will bifurcate proximal to the inferior border of the cricoid cartilage.⁵

It is critical to be aware of the occasional “direct” laryngeal nerve (also called the “nonrecurrent laryngeal nerve”). This anomaly results from abnormal embryonic development of the aortic arch. The anomaly is more common on the right (approximately 0.5% to 0.7%) than on the left (approximately 0.04%).⁶ On the right, a direct nerve is the consequence of the formation of the arteria lusoria vascular abnormality, in which the innominate artery is absent and the right common carotid and right subclavian arteries originate directly from the arch. The subclavian artery takes a retroesophageal course. To have a direct nerve on the left side, a number of other anomalies must exist. Specifically, the aortic arch must be right sided (as occurs in *situs inversus viscerum*), the origin of the left subclavian artery must be abnormally sited on the aortic arch, and the ligamentum arteriosum must be displaced to the right. A “false” nonrecurrent inferior laryngeal nerve has been described as a communicating branch between the cervical sympathetic system and the RLN, which can mimic a nerve

FIGURE 75.3. Cernea classification of the anatomic relationships between the external branch of the superior laryngeal nerve (EBSLN), the superior pole of the thyroid, and the superior thyroid artery. With type 1 anatomy, the nerve crosses the superior thyroid vessels 1 cm or more above the superior thyroid pole. With type 2 anatomy, the nerve crosses the vessels less than 1 cm above (type 2a) or even below (type 2b) the superior pole. Type 2 variants are the most vulnerable to iatrogenic injury.

that appears to emerge from the region of the vagus nerve as would a direct nerve.⁷

The superior laryngeal nerve arises from the vagus at the nodose ganglion near the base of the skull and descends along the course of the internal carotid artery. At the level of the hyoid bone, it divides into the internal branch (which enters the larynx at the thyrohyoid membrane to provide sensory innervation to the superior larynx) and the external branch (which provides motor innervation to the cricothyroid muscle). It has a variable course in relation to the inferior pharyngeal constrictor muscle and the branches of the superior thyroid artery. It is this fact that makes the external branch of the superior laryngeal nerve (EBSLN) vulnerable to iatrogenic injury. One classification of the anatomic variations is depicted in Figure 75.3.⁸

Lymphatic Relationships

The thyroid gland has intracapsular lymph channels, which provide some communication from lobe to lobe across the isthmus. A rich plexus of lymphatics surrounds the region of the thyroid; consequently, lymph flows in multiple directions from the gland. These factors are important to understand for treatment of thyroid malignancies. Within the anterior suspensory ligament is a small group of midline prelaryngeal lymph nodes known as the Delphian nodes. Along with the pretracheal and paratracheal nodes and those along the recurrent laryngeal nerves, these central compartment lymph nodes are classified as level VI. The upper jugular (level II), midjugular (level III), and lower jugular (level IV) lymph nodes divide the central compartment from the lateral compartment of the neck, whereas the posterior triangle lymph nodes are level V (Fig. 75.4). Thyroid cancers with regional lymph node metastases tend to involve level VI lymph node metastases before involving levels II, III, IV, and ultimately V.⁹ Level I (submental) and level VII

FIGURE 75.4. Classification scheme for regional lymph node basins in the neck.

(superior mediastinal) involvement is less common but can occur. Documented cases of “skip” metastases directly to the lateral compartment with no level VI involvement have been reported.¹⁰

Parathyroid Relationships

Parathyroid glands in typical locations are encountered during thyroidectomy by virtue of their association with the thyroid gland. Parathyroid glands in ectopic locations will typically not be encountered during thyroidectomy. The superior parathyroid gland is usually located in a relatively constant area largely because of the embryologic association between the lateral thyroid component and the superior parathyroid anlage (both associated with the fourth branchial pouch). The tubercle of Zuckerkandl is anatomically associated with the position of the ipsilateral superior parathyroid gland as well as the recurrent laryngeal nerve. In relation to the point at which the RLN intersects the inferior thyroid artery, a 2-cm circumscribed area on the cranial aspect will often contain the superior parathyroid gland. It may also be found tucked posterior to the inferior thyroid artery or even posteromedial to the superior thyroid pole. Superior parathyroid glands are very rarely found within the thyroid capsule. There is an 80% chance that a superior parathyroid gland will be found in a position similar to its contralateral partner.

The location of the inferior parathyroid gland may be more variable. It may be found on the anterior aspect of the inferior thyroid pole (especially with Hashimoto disease or large multinodular goiter) but is often on the inferolateral aspect. It may also be in the triangular region caudal to the inferior thyroid artery and anterior to the RLN. If it is not in these locations, it is often embedded in fat and thymic tissue within the thyrothymic tract. It may also be located under the thyroid capsule in an intrathyroidal position. The symmetry of inferior parathyroid glands from side to side is approximately 70%.

THYROID PHYSIOLOGY

Production of Thyroid Hormones

The thyroid gland produces thyroxine (T_4), triiodothyronine (T_3), and calcitonin under complicated regulatory mechanisms. Approximately 100 to 150 μg of dietary iodide is required for normal thyroid hormone synthesis to occur. In most developed regions of the world, daily intake from iodine-containing foods is usually far in excess of this requirement. The kidneys excrete the iodide not utilized by the thyroid. The availability of thyroid hormones to all tissues results from hormone production within the thyroid gland (specifically within the follicular cells) and the delivery and metabolism of the hormones in peripheral tissues. The integration of these systems to maintain a euthyroid state is ultimately orchestrated by the anterior pituitary gland through its secretion of thyrotropin (TSH). The active uptake of iodide in the thyroid occurs on the basolateral aspect of the follicular cells and is performed by a Na^+/K^+ -adenosine triphosphatase (ATPase)-mediated pump. Both TSH and the circulating concentration of iodide influence this symporter system. TSH acts within the thyroid gland to regulate the synthesis of thyroglobulin (Tg), the active uptake of iodide, its incorporation with tyrosine (an oxidative reaction catalyzed by thyroid peroxidase [TPO]), and the subsequent production of T_4 and T_3 (and their storage bound to Tg in the colloid component of the gland), and ultimately the release of both T_4 and T_3 into the circulation. Hormone release is an active process of micropinocytosis that involves resorption of the bound Tg into the follicular cell where enzymatic degradation releases T_4 and T_3 , which is released from the basal portion of the cell into the circulation. T_4 is produced in

preference to T_3 in the thyroid gland by a ratio of approximately 13:1 in normal states. T_4 has a relatively weak biologic action, so peripheral conversion to the more active T_3 hormone is required. Most of this takes place in the plasma and liver by type 1 deiodinase enzymes. All of the T_4 in the circulation is derived from the thyroid, whereas less than 20% of T_3 in the circulation is from the thyroid, the majority being produced enzymatically from monodeiodination of T_4 in nonthyroidal sites. In circulation, most thyroid hormone (>99% of both T_4 and T_3) is bound to proteins such as thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin. Protein-bound thyroid hormones are considered biologically inert because they do not enter cells until they are released from proteins to circulate in the very small free fraction. The half-life of T_4 is approximately 7 days, whereas the half-life of T_3 is much shorter—on the order of 8 to 12 hours.

Action of Thyroid Hormones

Thyroid hormones have many effects on various body tissues. The peripheral conversion from T_4 to T_3 increases the binding affinity of thyroid hormone for the nuclear thyroid receptor protein at least 10-fold. Triiodothyronine acts within the nucleus of peripheral tissues via four T_3 nuclear receptor subtypes to activate T_3 -regulated gene transcription. Ultimately, the physiologic actions of thyroid hormone relate to growth, differentiation, calorigenesis, and TSH suppression.

Calcitonin is a 32-amino-acid polypeptide that is physiologically effective in many other species, but in humans it is apparently less important. Although exogenous calcitonin may have a therapeutic effect, endogenous calcitonin secretion rarely results in an impact on serum calcium levels.

RELEVANT LABORATORY TESTS

An understanding of the normal relationship between free T_4 (FT_4) levels and TSH levels is critical for appropriate interpretation of thyroid function tests. Thyroid dysfunction can be determined directly, by measuring FT_4 levels, or indirectly, by measuring TSH. If TSH is to be used as the primary indicator of thyroid dysfunction, an intact hypothalamic-pituitary axis is required. Normally, a log/linear inverse relationship between TSH and FT_4 is defined by the negative feedback inhibition of TSH secretion by circulating thyroxine levels. Therefore, high TSH and low FT_4 levels are indicative of hypothyroidism and, conversely, low TSH and high FT_4 levels are characteristic of hyperthyroidism. It is likely that each individual has a genetically determined FT_4 set point. Early subtle deviation from that set point (via *in situ* conversion to FT_3 in the pituitary) will cause amplified changes in the TSH value, thus making TSH a very sensitive and clinically useful early indicator of incipient thyroid dysfunction.

Calcitonin

Basal calcitonin levels are generally less than 16 pg/mL for healthy people and for nearly all patients with thyroid disease, other than medullary thyroid carcinoma (MTC). Therefore, calcitonin serves as a very specific tumor marker for MTC. Basal calcitonin levels are useful for diagnosis and observation of these patients.

Free Thyroxine and Free Triiodothyronine

Technically, it is easier to measure the total (free + protein-bound) hormone levels (measured at nanomolar levels) as compared to the very small free hormone concentrations (measured

at picomolar ranges). Because T_4 is more tightly protein bound than T_3 , it is less bioavailable and, consequently, very difficult to measure directly. Ligand assays performed on automated immunoassay analyzers are fairly common in clinical use and are standardized against known hormone concentrations. Because this method does not rely on physical separation of the free and protein-bound hormone fractions, it is more accurately considered a free hormone estimate. The only reason to measure FT_4 or free triiodothyronine (FT_3) in preference to total thyroxine (TT_4) or total triiodothyronine (TT_3) is to improve the ability to detect thyroid dysfunction in the presence of thyroid hormone-binding abnormalities, which are relatively common. For example, some common drugs such as phenytoin, carbamazepine, furosemide, and aspirin may compete with thyroid hormone for binding to serum proteins.

Thyroglobulin

Serum thyroglobulin is reflective of three factors: the mass of thyroid tissue present; the presence of injury or inflammation of the gland, which allows leakage of Tg; and the degree of stimulation of the TSH receptor. The primary clinical use of Tg measurement is as a tumor marker, which serves as an index of the amount of differentiated thyroid cancer present (assuming that total thyroidectomy has been performed, thereby removing all normal thyroid tissue). Tg is measured in the serum by radioimmunoassay methods or by immunometric assays. The latter is more susceptible to competitive interference by thyroglobulin autoantibodies (TgAbs), which cause an artifactual decrease in the measured levels. In fact, sensitive quantitative TgAb determination is a critical accompaniment to serum Tg measurement, which is common during management of differentiated thyroid carcinoma (DTC). The particular assay utilized must be sensitive enough to detect Tg levels at the lower end of the reference range (1 to 3 $\mu\text{g/L}$) to be useful in monitoring for recurrence of DTC. It is critical to understand that the TSH level is a major influence on the level of Tg and, consequently, interpretation of any level requires an understanding of whether the patient was hypothyroid or not at the time of measurement.

Thyroid Autoantibodies

Measurement of thyroid peroxidase autoantibodies (TPOAbs) is the most sensitive test for detecting autoimmune thyroid disease. TPOAb is often the first abnormality to appear in Hashimoto disease; however, a significant fraction (up to 12%) of people with no apparent thyroid disorder may also have positive TPOAb titers.

TgAb may be present in approximately 3% to 10% of the general population and are even more common (20%) in patients with differentiated thyroid carcinoma. TgAb measurements are not as useful as TPOAb in evaluation of autoimmune thyroid disease.

Thyroid-stimulating hormone receptor autoantibodies (TRAbs) are heterogeneous and may mimic the action of TSH to cause hyperthyroidism as in Graves disease or, conversely, may block the action of TSH and cause hypothyroidism as occurs in neonates of a mother with thyroid autoantibodies. The specific different types include thyroid-stimulating antibodies (TSABs), TSH receptor-blocking antibodies (TBABs), thyroid growth-stimulating immunoglobins (TGIs), and thyroid binding inhibiting immunoglobulins (TBIs).

Thyroid-stimulating Hormone (Thyrotropin)

As the sensitivity and specificity of current TSH assays are quite high, the indirect approach of measuring TSH levels is the most sensitive method for detecting thyroid dysfunction.

The inverse relationship between TSH and FT_4 also dictates that small alterations in FT_4 will lead to a larger response in TSH, thus adding further support to this strategy. Modern methods are generally based on immunometric assays and are able to achieve a sensitivity of 0.02 mIU/L or less. At present, the upper limit of the normal range is considered to be approximately 5 mIU/L, but this is likely to be redefined at approximately 2.5 to 3.0 mIU/L in the future. This is because greater than 95% of rigorously screened normal euthyroid volunteers have values in this range, and it is becoming evident that many patients in the interval between these upper limit values progress to develop hypothyroidism, especially if thyroid autoantibodies are present. It is the range of 0.3 to 3.0 mIU/L that is generally considered the target range for TSH when patients are treated with levothyroxine (LT_4) for hypothyroidism because, consequently, most patients then have FT_4 levels in the upper third of the normal reference range.¹¹

Total Thyroxine and Total Triiodothyronine

Total hormone assays require an inhibitor to block or displace the hormone from its binding proteins. This factor, along with large sample dilution, allows binding of the hormone to the antibody reagent. Because of the 10-fold lower concentrations of T_3 in the serum, the TT_3 assay requires even greater sensitivity and precision. Because of variability in the quantity and the binding capacity of serum proteins, however, abnormal TT_4 and TT_3 measurements are more commonly caused by these factors instead of true thyroid dysfunction.

THYROID IMAGING TECHNIQUES

It is common for patients to present to the surgeon after having undergone multiple imaging tests. In general, only ultrasonography is routinely useful in evaluation of the patient with a thyroid nodule. In other specific circumstances, various other tests may be useful.

Nuclear Medicine Imaging

Radionuclide imaging is unique when compared with other thyroid imaging techniques in that the image provided depends on the specific functional characteristics of the thyroid tissue; however, it provides little anatomic detail.

Technetium Pertechnetate ^{99m}Tc Scintigraphy. ^{99m}Tc is the radionuclide most commonly available for thyroid imaging. The ^{99m}Tc pertechnetate component is actively trapped by functional thyroid cells in a manner similar to iodine but is not organified or stored in the thyroid. The isotope emits gamma (γ) radiation (the mechanism of scintigraphic imaging) and very small amounts of other types of radiation. Because the thyroid rapidly absorbs the injected ^{99m}Tc pertechnetate, imaging can occur early after administration and an entire study may take only an hour. A normal result demonstrates equal distribution bilaterally. Abnormal results include either concentration of the tracer in the region of a known nodule indicating an area of hyperfunction or, conversely, an area of photopenia (the "cold nodule") indicating a region of hypofunction. Before the era of fine-needle aspiration (FNA) biopsy, this finding increased the concern for potential malignancy.

^{123}I Iodine Scintigraphy. Because ^{123}I is trapped and organified by the thyroid gland, it can better indicate the functional characteristics of thyroid tissue. ^{123}I emits x-rays, some β particles, and γ rays. It has a short half-life of about 13 hours. After administration of an oral dose, the thyroid absorbs sufficient isotope to allow imaging by 4 hours. Images are also obtained

at 24 hours, and the total fraction of dose retained by the thyroid can then be calculated as the 24-hour radioactive iodine uptake (RAIU).

¹³¹Iodine Scintigraphy. ¹³¹I concentrates in the thyroid by the same mechanism as ¹²³I, but has a much longer half-life (about 8 days) and emits much more β radiation along with β radiation at a range that is suboptimal for clear image creation. However, because of its long half-life and thorough clearance from background tissues, it remains the isotope of choice for imaging of patients with differentiated thyroid carcinoma. Ultimately, treatment or ablation of residual or metastatic carcinoma (largely by the effect of β irradiation) is accomplished with higher doses of the isotope than required for imaging.

Positron Emission Tomography. ¹⁸F fluorodeoxyglucose positron emission tomography (PET) scanning with three-dimensional tomographic reconstruction can be very helpful in imaging thyroid carcinomas, and allows anatomic and functional evaluation. Because of the expense and the inconsistent insurance coverage, usage is currently limited to unusual circumstances such as recurrent thyroid malignancy that is otherwise occult (Fig. 75.5). The sensitivity in thyroid carcinomas is approximately 60% to 70%.¹² PET scanning is so frequently used in the evaluation of other solid malignancies that occult thyroid carcinomas are discovered in 2% to 3%.¹³ Incidentally discovered thyroid nodules identified on PET scans can be malignant in 14% to 47% and have a higher incidence of malignancy compared with nodules identified by other imaging modalities.^{13,14} Some overlap does occur for standard uptake values of benign and malignant nodules, so each nodule should be carefully evaluated.

^{99m}Tc Sestamibi Scintigraphy. Although ^{99m}Tc sestamibi scintigraphy is commonly used in localization of parathyroid tumors, it has incidentally been noted to concentrate in follicular tumors, most notably those with Hürthle cell cytology. For this

reason, it may have a role in localizing persistent disease in patients with Hürthle cell carcinoma. In contrast to radioactive iodine, however, it does not have therapeutic potential in ablating tissue. If a thyroid nodule is incidentally imaged on sestamibi scanning, there is no capability to predict whether it is a benign or malignant tumor.¹⁵

¹¹¹Indium-Octreotide Scintigraphy. Octreotide scanning (somatostatin receptor scintigraphy) has been occasionally useful in imaging differentiated thyroid carcinoma, especially when radioiodine scintigraphy has failed to do so. It is a useful imaging modality for patients with medullary thyroid cancer. Its therapeutic potential is undefined.

Ultrasonography

3 Ultrasound (US) has become the imaging technique of choice to evaluate the thyroid gland and its surrounding structures. It is best performed using a high-frequency “small parts” probe (7.5 to 15 mHz). It is the most sensitive and specific technique to determine the size, number, and distribution of thyroid nodules. US often detects very small, subtle nodules that are not otherwise clinically evident. Studied prospectively, the prevalence of asymptomatic thyroid nodules (thyroid incidentalomas) detected by ultrasonography is approximately 67%,¹⁶ whereas physical examination identifies thyroid nodules in approximately 5% to 8%. Hyperechoic nodules are often benign, whereas thyroid malignancies, regardless of cell type, are often hypoechoic. Irregular margins between the nodule and surrounding tissues raise concern for malignancy. An anechoic rim around the nodule is referred to as a “halo” sign and is much more likely to be associated with a benign nodule. Larger macrocalcifications with posterior acoustic shadowing are usually indicative of chronicity and are more likely associated with a benign nodule, whereas subtle microcalcifications, which cause a “twinkling” effect when the transducer is moved across the nodule, are correlated with malignancy. In practical terms, selective FNA biopsy should be limited to those nodules greater than 1 cm, those with concerning ultrasound features, or those that have increased in size under serial US measurement. Because US can detect nodules at a preclinical stage, it follows that proper perspective about the significance or insignificance of these nodules must be maintained. As with any imaging technique that depends on individual performance of the test, a user-dependent factor exists. US can be especially useful when performed by the surgeon and allows appropriate preoperative planning. Additionally, it has an important role in the preoperative staging and postoperative follow-up of patients with differentiated thyroid carcinoma. In experienced hands, it is a very sensitive technique for detecting abnormally enlarged lymph nodes or tumor recurrence within the thyroid bed, and for guiding subsequent confirmatory biopsy. It is especially important for identifying sites of recurrent thyroid cancer in those patients with negative radioactive iodine (RAI) scans or dedifferentiated tumors that are no longer iodine avid.

Cross-sectional Imaging

Computed tomography (CT) scans and magnetic resonance imaging (MRI) scans are useful in certain circumstances. In large nodules firmly fixed to contiguous structures or accompanied by new vocal cord paralysis, the concern for an invasive thyroid cancer is raised. CT scan may suggest invasion of the laryngeal or tracheal cartilages, which may modify the operative approach. Large goiters that have an obvious substernal component on physical examination or that are accompanied by an upper airway obstructive component may warrant preoperative CT scan to define the extent of the goiter, not only to help plan the specific operative plan but also to facilitate

FIGURE 75.5. ¹⁸F fluorodeoxyglucose (FDG) positron emission tomography scan of a patient with late recurrence of differentiated thyroid carcinoma in the mediastinum. The tumor is the intensely FDG-avid mass superior to the cardiac activity.

FIGURE 75.6. Example of a multinodular goiter with a large substernal component causing tracheal displacement and compression.

anesthetic evaluation for difficult airway management techniques such as fiberoptic intubation (Fig. 75.6).

FUNCTIONAL DISORDERS AND GENERAL TREATMENT CONSIDERATIONS

Hyperthyroidism

Hyperthyroidism can be caused by diverse pathophysiology, such as Graves disease, toxic multinodular goiter, and solitary toxic adenoma. Typical symptoms are heat intolerance, sweating, palpitations, tremor, hyperphagia, thirst, and sleep disturbances. Elderly patients can present with muscle wasting, atrial fibrillation, angina pectoris, or congestive heart failure. Regardless of specific cause, the need to control hyperthyroidism before operation is critical to prevent thyroid crisis (i.e., thyroid storm). Maximal safety is assured with thionamides combined with beta blockade, but studies suggest that propranolol or metoprolol used without thionamides are as safe and effective.^{17,18} Beta blockade alone is not universally accepted because of the occasional occurrence of postoperative thyroid crisis, tachycardia, hyperhidrosis, or anxiety. Doses of beta-blockers must continue through the morning of surgery and should not be stopped abruptly in the postoperative setting.

Graves Disease. Graves disease, which was described by Dr. Robert Graves in the 1830s as a toxic diffuse goiter associated with exophthalmos and palpitations, is an autoimmune disorder with a genetic predisposition and a female predominance (five to seven times greater than males). It is characterized by the presence of TSABs. These antibodies bind to the TSH receptor on follicular cells and stimulate thyroid hormone release. In addition, the autoimmune disease process may affect the eyes, causing exophthalmos secondary to inflammatory cell infiltration into the extraocular muscles and orbital connective tissue. Graves ophthalmopathy may be the first manifestation of disease, and it covers a wide spectrum from very mild changes in visual acuity or ocular dryness to obvious proptosis. It may be so severe as to require aggressive ophthalmologic treatment in approximately 5% of patients. Aside from the ophthalmopathic findings of proptosis and lid lag on physical examination, patients with Graves disease may have involvement of the pretibial regions, leading to myxedema. Patients with Graves disease usually have a diffuse goiter, which may be smooth or occasionally irregular. The gland is by nature very vascular and may occasionally have an audible bruit overlying it. T_4 and T_3

levels are increased and TSH levels are suppressed. The uptake of RAI generally shows a symmetrically enlarged gland with increased 24-hour RAIU measurements.

Three main treatment modalities for Graves disease are medical therapy, radioactive iodine treatment, and thyroidectomy. Selection of therapy depends on age, disease severity, goiter size, and patient preference. Practice patterns differ dramatically across the world, especially regarding the use of radioiodine (it is less common in Europe and especially Japan compared to the United States). The most common initial treatment involves thionamides and often beta blockade. In a small fraction of patients, antithyroid drugs may be the only therapy necessary, but in general, this strategy is considered an impermanent solution. Although the drugs may theoretically be used long term, they are associated with a small but real risk of life-threatening agranulocytosis. Additionally, a number of less severe side effects make tolerance difficult for many, and the recurrence of thyrotoxicosis can be unpredictable. Ultimately, most patients pursue a permanent or “ablative” therapy such as RAI or surgery. Treatment with RAI is very effective and has not been associated with secondary risk of development of a new malignancy, yet there is still hesitancy to use this treatment in young children. RAI may take up to 6 months to provide definitive results and thus antithyroid medications must continue during this period. In a small percentage of patients, a second treatment may be necessary. Although euthyroidism is the most common result of therapy, the effects are slowly progressive such that over 95% of patients become hypothyroid within 10 years following treatment. RAI therapy has been occasionally associated with exacerbation of Graves ophthalmopathy, although the effect is ameliorated by corticosteroids and the early addition of LT_4 posttreatment.^{19–21} Because of this concern, patients with severe ophthalmopathy should consider total thyroidectomy instead of RAI to prevent such an exacerbation; however, ultimate resolution of ophthalmopathy is no more likely with operation.

Surgery for Graves disease has the advantage of rapid correction of the hyperthyroid state. The specific operation has typically been either bilateral subtotal thyroidectomy or total thyroidectomy. Subtotal thyroidectomy attempts to remove enough tissue to resolve the hyperthyroidism but leave enough to maintain euthyroidism. Graves disease is dynamic and, thus, remissions and exacerbations are common. This factor makes the determination of exactly how much tissue to leave as a remnant very challenging (typically estimated between 4 and 8 g of thyroid tissue). For these reasons, total thyroidectomy is becoming the preferred operation for treatment of Graves disease with the intention of eliminating the chance of recurrence but accepting hypothyroidism requiring LT_4 therapy.

Toxic Multinodular Goiter. The term *toxic multinodular goiter* (MNG) refers to thyrotoxicosis that is caused by a multinodular goiter that may be of endemic or nonendemic etiology. H.S. Plummer first distinguished toxic adenomatous goiter from Graves disease. Although the eponym “Plummer disease” now more commonly refers to the patient with a solitary toxic nodule (see later), many clinicians still include toxic MNG under the same historical blanket. Thyrotoxicosis may occur as a progression from euthyroid multinodular goiter that was originally TSH dependent, which then progressed to a state of autonomy whereby it is not suppressible with LT_4 . After that, it may progress to a toxic state in which distinct nodular areas are overproducing T_4 and T_3 with resultant TSH suppression. Although the cause is clearly distinct, it is possible that some patients included in this diagnostic category actually have Graves disease with nodular degeneration of their diffuse goiter. Patients with toxic MNG, however, are often easily distinguished from those with Graves disease. The typical patient is female and more than 50 years old with a previous history of multinodular goiter. Thyrotoxicosis may be precipitated in a MNG with or without areas of autonomy when an iodide load is provided (Jod-Basedow phenomenon).

Historically, public health efforts to iodinate salt or flour in an iodine-deficient population have caused this to follow over a period of years. This can occur after exposure to iodinated radiographic contrast media, expectorants, or iodide-containing drugs such as amiodarone.

Hyperthyroidism present in a patient with MNG can involve a wide spectrum of severity such that it is not uncommon for a patient having indications for thyroidectomy, for reasons such as continued nodular growth or substernal extension, to have a suppressed TSH in the absence of major functional symptoms. This subclinical thyrotoxicosis is another potential indication for thyroidectomy because it rarely resolves spontaneously and prolonged hyperthyroidism, even when mild, may have deleterious health effects. Thyroidectomy is a relatively common treatment for toxic MNG, with radioiodine treatment representing a less common alternative because it often requires high doses or repeated treatments because of the large goiter size and low radioiodine uptake. Long-term remissions from antithyroid drug treatment are even less common or predictable than in treatment of Graves disease.²²

Solitary Toxic Adenoma. Patients with thyrotoxicosis and a dominant thyroid nodule may have a toxic adenoma. Nodules usually grow to at least 2 cm in size before hyperthyroidism is clinically evident. As expected, T_3 or T_4 or both are elevated and TSH is suppressed. Thyroid scintigraphy will demonstrate a single “hot” area corresponding to the known nodule with suppression of the remainder of the thyroid substance. FNA is rarely helpful and the incidence of malignancy within these nodules is negligible. Treatment options include ^{131}I RAI therapy or resection. RAI is effective in controlling the hyperthyroidism, but depending on nodule size, may leave behind a palpable abnormality. In particular, younger patients with sizable nodules may choose operation. The resection is typically a hemithyroidectomy and isthmusectomy. The contralateral lobe is often normal and will maintain normal thyroid hormone production after the hyperthyroidism is remedied.

Hypothyroidism

Primary hypothyroidism can arise from intrinsic thyroid disease, iatrogenic thyroid removal or destruction, and antithyroid drug effects. Secondary hypothyroidism can also occur from failure of thyrotropic function (via TSH) of the pituitary gland because of disease, removal, or destruction of that gland as well. Rarely, tertiary hypothyroidism can occur with destructive disorders of the hypothalamus via decreased production of thyrotropin-releasing hormone. The most common cause of primary hypothyroidism in adult patients is Hashimoto thyroiditis. In large part, hypothyroidism is straightforward to address with exogenous LT_4 therapy, with the exception of the patient with thyroid hormone resistance. As defined by hypothyroidism itself, the role for surgical therapy is limited. A structural thyroid disorder associated with the hypothyroidism, however, may be an indication for thyroidectomy (e.g., goiter).

Thyroiditis

A summary of conditions causing a painful neck mass is delineated in Table 75.1. Inflammatory conditions of the thyroid are a disparate family of conditions that require surgical therapy in the minority of situations. However, they can be quite prevalent in patients undergoing evaluation for thyroid surgery and a thorough understanding is required to avoid diagnostic and therapeutic misadventures.

Hashimoto Thyroiditis. Also known as chronic thyroiditis, autoimmune thyroiditis, and lymphocytic thyroiditis, this condition was described by Hashimoto in 1912 as struma

TABLE 75.1

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS OF THE PAINFUL NECK MASS

THYROIDAL CAUSES

Acute thyroiditis
Subacute thyroiditis
Acute thyroid cyst (hemorrhage into cyst or nodule)
Rapidly enlarging thyroid carcinoma
Painful Hashimoto thyroiditis
Radiation thyroiditis

NONTHYROIDAL CAUSES

Infected thyroglossal duct cyst
Infected branchial cleft cyst
Infected cystic hygroma
Cervical adenitis
Globus hystericus (no mass palpable)

Adapted from Farwall AP, Braverman LE. Thyroiditis. In: Randolph GW, ed. *Surgery of the Thyroid and Parathyroid Glands*. Philadelphia, PA: WB Saunders; 2003:49.

lymphomatosa based on the histologic findings. It affects approximately 10% of the general population and is the most common cause of both goiter and hypothyroidism in the United States. Although it can occur at nearly any age, the peak is from age 30 to 60. Female-to-male preponderance is as high as 9:1. It is clearly an autoimmune condition and there is a moderate genetic predisposition, associated with human leukocyte antigen (HLA)-DR3, -DR5, and -B8. The disease prevalence is increased in iodine-sufficient regions and this may be because immunogenicity of the thyroglobulin molecule increases with the degree of iodination. The histologic changes are characterized by lymphocytic infiltration with fibrosis and germinal centers. Some follicular cells may undergo metaplasia to Hürthle cells. The typical presentation is that of a painless diffuse goiter in a young woman discovered on physical examination associated with or without hypothyroidism. Patients often note a sense of fullness in, or awareness of, the region of the thyroid. When the associated goiter is large, compressive symptoms of dysphagia or dyspnea may occur. The goiter is typically firm and rubbery and slightly “bumpy” with prominent lateral lobes. Nodular disease can and does occur in a gland affected by Hashimoto disease and needs to be investigated with FNA to rule out coexisting malignancy, typically papillary cancer or, rarely, thyroid lymphoma. Some data suggest that Hashimoto disease may actually be a risk factor for papillary thyroid cancer.²³ Thyroid autoantibody titers are elevated, TPOAb primarily and TgAb secondarily. In approximately 5% of patients, a transient phase of hyperthyroidism, termed “Hashitoxicosis,” occurs at the onset of disease and the subsequent pattern in thyroid function changes are nearly indistinguishable from that of silent thyroiditis. Many patients are hypothyroid, but they may be euthyroid at the time of presentation. If so, approximately 5% per year will progress to hypothyroidism.²⁴ For the majority of patients, treatment of Hashimoto thyroiditis is limited to LT_4 therapy in those with hypothyroidism. Surgery is indicated in patients with large goiters, significant compressive symptoms, local symptoms refractory to LT_4 therapy, or the inability to rule out malignancy (typically in the setting of nodules or rapid growth).

Painless or Postpartum Thyroiditis. Sporadic silent (painless) thyroiditis and postpartum thyroiditis are known as destruction-induced thyroiditis and are probably variants of

the same process, distinguished only by the relationship to pregnancy.²⁵ Along with subacute thyroiditis, these conditions are characterized by the onset of thyrotoxicosis and a goiter, and low 24-hour RAIU. Even excluding postpartum cases, there is a female predominance by 2:1 and the age range of affected patients is broad. The cause appears to be autoimmune, but the genetic predisposition is low. There is no fever or malaise and the goiter is painless but persistent. Thyroid autoantibody titers are often high, and the erythrocyte sedimentation rate (ESR) is usually normal. Thyroid function is dynamic and follows a pattern similar to that of subacute thyroiditis with the abrupt onset of thyrotoxicosis followed by a period of euthyroidism, then hypothyroidism. Permanent hypothyroidism is fairly common. A 24-hour RAIU is very low (usually <5%), consistent with a thyroid gland that is damaged on the cellular level. At the histologic level, lymphocytic infiltration is present along with destruction of follicular cells. If it is pregnancy associated, it is likely to relapse with future pregnancies. If symptoms of thyrotoxicosis are significant, β -adrenergic-blocking drugs may be used, but antithyroid drugs are not appropriate because the gland is not hyperfunctioning at the follicular cell level. If LT₄ therapy is instituted during the hypothyroid phase for symptomatic relief, it can be withdrawn after 6 to 9 months to determine if recovery has occurred.

Subacute Thyroiditis. Subacute thyroiditis is a common form of thyroiditis that affects women more often than men by a 5:1 ratio and often in the age group of 20 to 60. There are a number of synonymous terms, such as de Quervain thyroiditis, giant cell thyroiditis, pseudogranulomatous thyroiditis, subacute painful thyroiditis, and subacute granulomatous thyroiditis. The cause is not entirely certain, but it appears to be virally related. There may be moderate genetic predisposition. A prodrome consistent with an upper respiratory viral infection is very common. The patient often has fever and malaise and an exquisitely painful and firm goiter that is also transient. The goiter is usually unilaterally dominant, and the patient may have pain that radiates to the ipsilateral ear. Giant cells (which may also be observed on FNA, thus supporting the diagnosis) and granulomas often infiltrate the thyroid. It is common to identify a dynamic picture of thyroid function with subclinical or obvious thyrotoxicosis followed by hypothyroidism, which may occasionally be permanent. Consistent with follicular cell destruction, serum Tg levels may be elevated. Antithyroid antibodies may be present in low titers and the ESR is often high. A 24-hour RAIU is usually quite low (<5%). Management is similar to painless thyroiditis in that beta-blockers may be used, but antithyroid medications are not useful. Salicylates or nonsteroidal anti-inflammatory drugs (NSAIDs) are adequate to control pain in most cases, with the occasional need for oral glucocorticoids. Although the course of disease can be protracted for weeks or months, relapse is rare and management is usually limited to management of symptoms.

Amiodarone-induced Thyrotoxicosis or Thyroiditis.

Although the significance of amiodarone-induced thyrotoxicosis or thyroiditis is usually related to the thyrotoxicosis induced by the Jod-Basedow mechanism, increased understanding of the condition has led to the realization that it often includes a component of destructive thyroiditis as well (common in the United States), especially when background iodine deficiency is not a factor.²⁶ The antiarrhythmic drug amiodarone is 37% iodine by weight and the iodine load can induce thyrotoxicosis. Amiodarone therapy results in thyrotoxicosis in 3% of patients in iodine-sufficient regions and up to 10% of patients in iodine-deficient regions.²⁷ In addition, the drug inhibits 5'-deiodinase. Medical treatment of the hyperthyroidism is difficult because of both the long half-life of the drug and the decompensation in cardiac function related to underlying heart disease. Two types of amiodarone-induced hyperthyroidism can occur, but distinction between the types can be clinically difficult. Type I is iodine

induced and is more common in iodine-deficient areas (type Ia is often associated with preexisting multinodular goiter). In general, amiodarone should be stopped and thionamides may be variably effective. A 24-hour RAIU may be normal or elevated in iodine-deficient areas (allowing that therapeutic possibility), but in iodine-sufficient areas (type Ib is often associated with Graves disease), 24-hour RAIU is decreased. Type II, defined primarily by destructive thyroiditis, usually occurs in iodine-sufficient areas and can be self-limited. Decreased thyroid parenchymal blood flow on color flow Doppler imaging is typical. A 24-hour RAIU is typically very low and serum interleukin-6 may be elevated. Corticosteroids are used therapeutically and, if tolerated, beta-blockers as well. If hyperthyroidism is severe in either type I or II, thyroidectomy may be required to resolve the thyrotoxicosis and allow continuation of amiodarone. Some recommend iopanoic acid before thyroidectomy, which markedly inhibits peripheral conversion of T₄ to T₃. Because of the cardiac decompensation, thyroidectomy may need to be done under local anesthesia and sedation to avoid the risks of general anesthesia.

Acute Thyroiditis. Acute thyroiditis refers to a rare suppurative condition caused by bacterial organisms. It may occur in children or young adults (approximately age 20 to 40 years) with equal sex predisposition and no evidence of genetic predisposition. Patients with acquired immunodeficiency syndrome (AIDS) may be at risk for this condition. A clinical prodrome, usually a viral or bacterial upper respiratory infection, may occur and the patient is often affected by a significant fever and malaise and may have radiating pain to the region of the ipsilateral ear. *Staphylococcus aureus* and *Streptococcus pyogenes* are the most common pathogens. A painful but ultimately transient goiter may be evident, which often is a thyroidal or perithyroidal abscess. The patient usually remains euthyroid and antithyroid antibody titers are normal. ESR may be elevated. If a 24-hour RAIU scan is performed, it is often normal but uptake may be focally decreased in the region of active infection. Bacterial infection of the thyroid may occur via hematologic spread from a distant site or local infiltration from other head and neck infections. If acute thyroiditis is related to a fistulous communication with the pyriform sinus, the condition may recur repeatedly. It is the potential for abscess formation or pyriform sinus fistula that makes this a disease that occasionally requires surgical intervention even if FNA is able to determine the causative organism and if appropriate parenteral antibiotics are instituted.

Riedel Thyroiditis. Also known as Riedel struma or invasive fibrous thyroiditis, this rare disorder affects mainly women (by a ratio of 4:1) and usually occurs between the ages of 30 and 60. The cause is unknown and a genetic predisposition is not apparent. The patient presents with a painless but persistent, and often progressive, goiter. Patients are usually euthyroid at presentation but may eventually become hypothyroid. They may have detectable antithyroid antibody titers and a normal ESR. If obtained, the 24-hour RAIU is often normal or somewhat decreased. Physical examination reveals an exceptionally firm goiter often described as "woody." Most commonly, this is a diffuse, bilobar process. Histologically, the disease is characterized by extensive fibrosis, which may progress to a point of compression of adjacent structures such as the trachea and esophagus. Riedel thyroiditis is often accompanied by other equally mysterious focally sclerotic conditions such as retroperitoneal fibrosis, mediastinal fibrosis, retro-orbital fibrosis, and sclerosing cholangitis.²⁸ Because of its infiltrative nature, it is important to differentiate Riedel thyroiditis from thyroid carcinoma. FNA is often inadequate and open biopsy may be required. If substantial compression exists, surgery is often required to relieve these symptoms. Extensive resection is often unsafe or impossible, and wedge resections, especially of the isthmus, may be very effective in relieving symptoms. Medical

therapy, including corticosteroids, methotrexate, or tamoxifen, may have a positive impact in the chronic setting.²⁹

NODULAR THYROID DISEASE AND GENERAL TREATMENT CONSIDERATIONS

Nontoxic Multinodular Goiter

From a world health perspective, endemic goiter is still a significant issue. Endemic goiters are caused by dietary iodine deficiency, which ultimately is also responsible for endemic cretinism—another major world health issue. Goitrogenic substances found in diets may also be contributory. Iodine deficiency in a region is addressed over time by iodination of dietary components (e.g., salt, bread flour, or vegetable oil).

In endemic goiter, T_4 levels may be normal or decreased, whereas T_3 levels are normal or often increased. This reflects an adaptive regulatory mechanism by which the thyroid preferentially shifts production to the more biologically potent T_3 . Exogenous thyroxine therapy will induce a decrease in goiter size in roughly 80% of patients treated. Resection may be indicated for large size, increase in size while on T_4 , or compression of the trachea, esophagus, or superior vena cava.

In most developed countries, the term *goiter* generically refers to the group of diseases causing thyroid enlargement in patients not affected by iodine deficiency. In common usage, *goiter* typically refers to patients with nodular goiter. Asymptomatic multinodular goiter is common, and if reasonable assurance that the goiter is not harboring a malignancy can be obtained by FNA, thyroidectomy is not usually indicated. Sometimes, because of the number of nodules of significant size (>1 cm), repeated FNA during longitudinal observation becomes impractical. Patients may grow frustrated with the process of multiple FNAs and elect to undergo thyroidectomy to simplify management. Compressive symptoms involving the airway or esophagus are also an indication for thyroidectomy. A multinodular goiter causing subclinical or obvious thyrotoxicosis (toxic multinodular goiter) should also be removed. Total thyroidectomy is the procedure of choice because of the significant chance for recurrent nodular degeneration of the thyroid remnant after subtotal thyroidectomy and the attendant increase in morbidity during reoperation. If a goiter develops in a substernal position, thyroidectomy is warranted because of the inability to monitor continuing growth in the mediastinum. If tracheal compression develops gradually, it may be largely asymptomatic until a critical point of narrowing is reached, which inhibits passage of air in a sudden and catastrophic manner. Because all of the important attachments to the thyroid parenchyma remain in the neck, even very large substernal goiters can be removed through a cervical incision. Less than 5% will require partial sternotomy for full removal.³⁰

Solitary or Dominant Thyroid Nodule

Nodular thyroid disease is very common, whereas thyroid malignancy is relatively rare. The prevalence of thyroid nodules is approximately 4% to 7% in the general population; however, thyroid nodules are in fact present in up to 60% of patients undergoing autopsy. In contrast, the population incidence of thyroid cancer has increased from 3.72 to 12.08 cases per 100,000 person-years.³¹ This increase is only partially explained by improved surveillance. Appropriately identifying patients with malignancy who require operation while appropriately avoiding operation for the majority of patients with benign, noncompressive nodules can be a difficult task.

When assessing a patient with a solitary thyroid nodule, the physician should first query factors in the history that may indicate the likelihood of benign or malignant disease. A new thyroid nodule that occurs at the extremes of age is more likely to be malignant than one that occurs in the third through seventh decades. The risk of a solitary thyroid nodule in a child under 14 being malignant may be as high as 50%.³² Patient gender itself does not generally confer risk of malignancy, and the fact that thyroid cancer occurs in a greater number of women than men is related somewhat to the increased prevalence of nodular thyroid disease in women. A new thyroid nodule that occurs after the age of 60, however, is more likely to be malignant in a man than in a woman.

Many factors apparent on physical examination or imaging can also be used to assess the potential for malignant disease in the patient with a thyroid nodule. The consideration that nodular disease is uninodular (e.g., solitary) instead of multinodular has traditionally implied that the former situation is more concerning for malignancy. Especially in the era of thyroid US, this distinction is overemphasized because at least half of nodules considered solitary by clinical examination are ultimately found to be a dominant nodule within a multinodular goiter. It is mostly a practical consideration that the dominant nodule (largest or most apparent) of a multinodular gland is the one that dictates subsequent clinical decision making. The characteristics of a nodule assessed by physical examination (size, firmness, texture) have a limited ability to predict malignancy. Significant fixation to surrounding tissues can heighten the level of concern. Associated lymphadenopathy in the central or lateral cervical compartments is certainly concerning for potential malignancy. Although many patients with benign thyroid disease describe hoarseness or a change in voice, this is often largely subjective and is of limited concern unless accompanied by objective hoarseness and ipsilateral recurrent laryngeal nerve paralysis. Thyroid functional status can be important in two ways. First, if the nodule is truly solitary and the patient is hyperthyroid, it may be a toxic autonomous nodule. If this is confirmed by nuclear scintigraphy, the risk of malignancy in this nodule is negligible. If the patient is chronically hypothyroid (likely from Hashimoto disease), a firm, rapidly enlarging, indistinct nodule raises the possibility of the presence of an extranodal lymphoma or anaplastic thyroid cancer.

A critical question in assessing any patient with a thyroid nodule is whether any history of radiation exposure exists. At least 90% of radiation-associated thyroid cancers are of the papillary type. Typical exposures to radiation in the 1940s and 1950s included external beam irradiation treatment for acne, tinea capitis, external otitis, recurrent tonsillitis, or neonatal thymic enlargement. In the current era, excessive diagnostic radiation or high-dose therapeutic irradiation (e.g., treatment of lymphoma or head and neck malignancies) is responsible for relevant exposures. The association is well documented and there appears to be a linear relationship between the dose of radiation and the risk for thyroid cancer, with even a higher risk among those exposed at a young age.³³ The typical latent period between exposure and clinically evident cancer appears to be in the 3- to 8-year range. It is not clear when, if ever, the risk is no longer present. Cases appear to increase for up to three decades after exposure and then begin to tail off. Another source of radiation exposure to the thyroid gland is nuclear fallout, related to either atomic weapons or nuclear power plant accidents, such as Chernobyl in 1986, which exposed 1.5 million people in southern Belarus and northern Ukraine. This acute γ -radiation exposure is likely the main risk factor, but longer-term exposure to diverse radioisotopes of iodine that secondarily contaminate the regional water and food supplies may also be contributory.

Another critical question to investigate is whether a family history of thyroid cancer or associated conditions exists. The key issue is to uncover a family history of medullary thyroid cancer, which suggests the potential for an inherited syndrome

such as familial medullary thyroid carcinoma or multiple endocrine neoplasia type 2. Papillary thyroid cancer, however, may have a familial association as well, either independently or, more commonly, associated with Cowden syndrome or Gardner syndrome (familial adenomatous polyposis).

In most situations, extensive thyroid function testing is not necessary and a TSH is all that is required. After initial clinical assessment, thyroid nodular disease is often assessed by US. Relevant factors include the size of the nodule and other sonographic characteristics previously explained. Also important is whether the nodule is truly solitary or whether there are additional nodules, especially in the contralateral lobe, which may affect the specific surgical recommendations. Although it is not uncommon for patients to undergo thyroid scintigraphy, its utility is actually very limited and should not be routinely used to evaluate thyroid nodules. The only helpful role is to determine the specific nature of a nodule in a patient with hyperthyroidism. The additional diagnostic information provided by knowing the nodule is “cold” or “photopenic” is very limited, especially in the era of US and FNA, which can characterize the potential for malignancy to a much greater degree. Although smaller cysts may resolve with aspiration, recurrence is very likely if the cyst is 4 cm or greater and, consequently, resection should be considered.

FNA is the cornerstone of diagnostic evaluation of the thyroid nodule. It can reliably identify colloid nodules, benign nodular hyperplasia, thyroiditis, papillary thyroid carcinoma (PTC), medullary thyroid carcinoma, and anaplastic thyroid carcinoma. FNA may suggest an extranodal lymphoma, but usually more tissue for diagnosis and flow cytometry is required. FNA can also classify nodules as follicular lesions or Hürthle cell lesions. These lesions are indeterminate and currently require at least partial thyroidectomy (e.g., lobectomy) to determine whether it is a follicular (or Hürthle cell) adenoma or follicular (or Hürthle cell) carcinoma. Determination of malignancy in these lesions can be made only by the demonstration of capsular or vascular invasion. FNA should have a false-positive rate of 0% to 0.5% and a false-negative rate of 0% to 5%. The potential for a nondiagnostic interpretation is directly related to the number of follicular cells recovered for analysis. This is ultimately related to technique and the number of needle passes performed. US guidance can help ensure that the biopsy results are representative of the nodule of interest.

Standard disposable needles ranging in size from 23 to 27 gauge and 10-mL syringes are used. The target nodule is located using ultrasound guidance while multiple passes through the most concerning appearing solid portions of the nodule are made. An average of three separate biopsy maneuvers is reasonable practice. The technique does not rely heavily on aspiration or suction as the name might imply. The ideal sample remains mostly in the needle hub and barrel before expelling it onto a slide or into fixative for cytologic preparation. Current limitations require that decisions based on FNA are contingent on the cytologic appearance. It is likely that in the near future, however, specific molecular markers or gene expression data will be identified that will allow specific testing of FNA specimens to indicate risk of malignancy.

THYROID MALIGNANCY AND GENERAL TREATMENT CONSIDERATIONS

General Considerations

Thyroid cancers exhibit a wide spectrum of behavior, from the inconsequential, occult, well-differentiated thyroid carcinoma to the nearly uniformly fatal undifferentiated anaplastic cancers. Fortunately, at least 98% of thyroid cancers are well differentiated and long-term prognosis is excellent. Although the

general treatment strategy for thyroid carcinomas is familiar (surgical resection, staging of disease, appropriate adjuvant treatments, and secondary screening or follow-up), a number of unique points are emphasized below.

Tumor Classification

Differentiated thyroid cancers are of follicular cell origin (papillary thyroid carcinoma and its variants, follicular thyroid carcinoma, and Hürthle cell carcinoma) or parafollicular (C-cell) origin (medullary thyroid carcinoma). There is a spectrum of dedifferentiation that exists between these tumors and undifferentiated cancers such as anaplastic carcinoma. Tumors such as insular or tall cell variants exist along this spectrum. In a general sense, prognosis is directly related to the degree of differentiation. A number of classification systems exist. The American Thyroid Association (ATA), the Armed Forces Institute of Pathology (AFIP), and the World Health Organization (WHO) all consider papillary thyroid cancers (including classic papillary carcinoma, mixed papillary-follicular variants, follicular variants, and follicular thyroid carcinomas [FTC]) as differentiated thyroid cancer. Still, some disagreement exists about the classification of Hürthle cell carcinomas (HCCs). In general, the ATA and WHO consider HCC as a subtype of follicular thyroid carcinoma, although the AFIP does not. Support for considering HCC as a subtype of follicular thyroid carcinoma includes the histologic demonstration of the transition of follicular to Hürthle cells, an intact TSH receptor adenylate cyclase system in Hürthle cells, and the ability of Hürthle cells to produce thyroglobulin and thus maintain Tg positivity on immunohistochemical staining.³⁴ Other characteristics, however, such as higher oncogene expression in HCC than FTC and the general impression that HCC can display a more aggressive clinical course than FTC cause some to classify HCC tumors outside the FTC family.³⁵ Medullary thyroid carcinoma is also a differentiated thyroid carcinoma but is of parafollicular cell origin.

Papillary Thyroid Carcinoma. Papillary thyroid carcinoma (PTC) accounts for approximately 80% of thyroid carcinomas. Although it occurs across a wide spectrum of ages from childhood to the elderly, the peak incidence begins in the third and fourth decades of life. It is more common in females than males. It is especially prevalent in iodine-sufficient regions of the world. Papillary carcinoma arises from the follicular cells, is characterized by papillary architecture, and is often associated with calcifications, psammoma bodies, squamous metaplasia, and fibrosis. Cytology is diagnostically important and typical findings include large, overlapping nuclei that are optically clear (known as Orphan Annie nuclei) and intranuclear grooves. As a whole, the prognosis is excellent, especially in those patients with tumors that define a low risk for recurrence. Greater than 30% of PTC is multicentric and found throughout the thyroid. Although multifocality does not signify a worse prognosis, this characteristic, in part, influences the rationale for total thyroidectomy discussed later. The incidence of cervical lymph node metastases varies across series and is influenced by whether lymphadenectomy is performed for prophylactic or therapeutic reasons. In general, it approximates 30% to 40%. Distant metastases occur in 2% to 14% of patients with PTC.³⁴ At least 70% of PTC can take up radioiodine and thus, RAI scanning is an important part of the treatment strategy.

Variants. A follicular variant of papillary thyroid carcinoma essentially combines the histologic and architectural appearance of follicular tumors with the cytologic features of papillary carcinoma. In terms of treatment and biologic behavior, this variant behaves in the same manner as classic PTC. The dilemma caused by this variant is based on the fact that, in contrast to classic PTC, it is very difficult to diagnose on frozen section analysis. It is often interpreted as a follicular

lesion with the final diagnosis deferred until formal histopathology can be completed to identify the atypical features. More aggressive variants of papillary carcinoma include tall cell and columnar types, which also exist along the spectrum of dedifferentiation.

Microcarcinoma. PTCs less than 1 cm in size are considered microcarcinomas (occult or incidental tumors). They may be multifocal and are usually clinically silent until thyroidectomy is performed for another indication. Although they are by definition malignant, this group of tumors requires a different set of considerations based on “nonmalignant” biologic behavior and patient outcome. Prognosis is exceptionally good, with a 0.4% cause-specific mortality rate.³⁶ If such a solitary microcarcinoma is found after lobectomy, adequate treatment has already been rendered and completion thyroidectomy or radioiodine scanning or both are not typically indicated. Somewhat in contrast, if these microcarcinomas are diagnosed preoperatively, which may be difficult because of their small size, thyroid resection is usually recommended. Some groups, however, have chosen to follow these patients closely with ultrasound. Approximately 70% do not increase in size significantly.³⁷ Nonetheless, these tumors cannot be completely discounted. Metastases to central neck (level VI) lymph nodes occur, and it is not uncommon for PTC to be diagnosed by biopsy of a lateral compartment lymph node even if the associated primary tumor is not apparent. If these patients are treated with total thyroidectomy, very careful histologic sectioning will be required to find the associated primary tumor, which may be as small as 1 mm.

Follicular Carcinoma. FTC accounts for approximately 10% to 20% of all thyroid cancers. Again, there is a female-to-male predominance, and the incidence begins to increase in the fifth decade of life. Determination that a follicular lesion/neoplasm is a carcinoma is contingent not only on the specific cellular architecture but also on the findings of vascular and capsular invasion. This determination is rarely able to be made on frozen section and the information is often not available until final histopathology results.³⁷ FTC is often more advanced at the time of diagnosis compared with PTC. It is more common for FTC to be locally infiltrative of muscles and perithyroidal vascular structures. Because of this difference in stage at diagnosis, the overall 10-year survival for patients with FTC is slightly worse than for those with PTC, but when patients are matched for age and stage with PTC, this difference largely disappears.³⁸ In contrast to PTC, follicular cancers are usually solitary. Approximately one third of patients with FTC have distant metastases at the time of diagnosis and the pattern is consistent with a mechanism of hematogenous spread, with lung and bone most often being involved. Lymph node involvement is limited to only about 10% of patients. Importantly, at least 80% of FTC will take up radioiodine.

Minimally Invasive Follicular Carcinoma. Follicular neoplasms with demonstrable capsular invasion but no vascular invasion are classified as minimally invasive follicular cancers. These patients have an excellent prognosis, conceptually equivalent to patients with incidental papillary microcarcinomas. If such a tumor is found after hemithyroidectomy, there is no reason for most patients to undergo completion thyroidectomy and radioiodine scanning as would be recommended for true FTC.³⁹

Hürthle Cell Carcinoma. Malignant Hürthle cell neoplasms account for approximately 5% of thyroid carcinomas and, in general, occur in patients slightly older than those with PTC or FTC. Despite their relatively uncommon nature, HCC enters diagnostic consideration frequently because Hürthle cells are frequently present on FNA cytology from thyroid nodules. Patients with Hashimoto disease or colloid nodules commonly demonstrate Hürthle cells; however, it is the nodule

that contains almost entirely Hürthle cells that raises concern for HCC. If HCC is suggested by FNA cytology, a diagnostic thyroid lobectomy at the minimum is required to definitively establish the nature of the tumor. Hürthle cell adenomas (neoplasms with no evidence of capsular or vascular invasion) certainly exist, but occasionally a tumor that is otherwise histologically compatible with a Hürthle cell adenoma is found to be associated with lymph node or distant metastases. For these reasons and considering the perspective that HCC may behave more aggressively, many surgeons advocate total thyroidectomy for any Hürthle cell neoplasm.⁴⁰ HCC is more prevalent in women than men and is more often associated with lymph node metastases and distant metastases than PTC and FTC in general. Although it is a DTC likely of follicular cell origin, very few HCC tumors take up radioiodine (approximately 10%). For this reason, and taking into consideration the more aggressive nature of HCC, complete surgical resection is especially important in this disease. Therefore, total thyroidectomy is often combined with central compartment lymphadenectomy and perhaps modified radical neck dissection if lateral compartment lymph node involvement is evident.

Medullary Carcinoma. MTC arises from the parafollicular C cells and accounts for about 5% to 7% of all thyroid malignancies. Approximately 75% occur in a sporadic fashion and 20% to 25% may be familial (multiple endocrine neoplasia [MEN] types 2A and 2B, as well as familial medullary thyroid carcinoma [FMTC]). These are autosomal dominant inherited endocrinopathies related to a group of specific mutations on chromosome 10q11.2 (RET proto-oncogene) (Table 75.2). The familial forms of MTC have different degrees of aggressiveness related to the specific syndrome. Familial MTC has the most indolent course, whereas MEN 2B has the most aggressive course, with MEN 2A intermediate to these. Most sporadic MTC is relatively slow growing and may be quite indolent. Typically, these patients do not present before 30 years of age. A subset of patients with sporadic MTC have a much more aggressive course. This variability in biologic behavior accounts for the overall 10-year survival rate of approximately 50%. Overall, MTC is more aggressive than other DTCs and is more likely to metastasize. At least 50% to 75% of patients with sporadic MTC have nodal metastases already present at the time of diagnosis. To some degree this is correlated with tumor size and contralateral cervical metastases are conceptually systemic disease.⁴¹ Distant metastases may involve the liver, lungs, and bone. FNA can be diagnostic for medullary cancer, especially if the specimen is stained for calcitonin. MTC is unique in that calcitonin is a very specific tumor marker used for diagnosis and to guide subsequent follow-up. Most MTCs also make carcinoembryonic antigen (CEA).

Approximately 20% of patients thought to have sporadic MTC may in fact be index cases of familial MTC. Therefore, any patient with a new diagnosis of MTC should have genetic testing for the RET proto-oncogene mutations associated with MEN 2 and FMTC. Appropriate screening for pheochromocytoma (which would be treated prior to thyroidectomy) and hyperparathyroidism are required.

The treatment strategy for MTC is somewhat distinguished from that of DTC of follicular cell origin. Because of the high likelihood of lymph node metastases and the fact that there is no effective adjuvant therapy (MTC does not take up radioiodine), more extensive initial surgical resection is warranted. With few exceptions, the appropriate operation for MTC is a total thyroidectomy with central compartment lymphadenectomy (level VI). Because intraoperative assessment of lymph node involvement is relatively inaccurate, consideration should be given to ipsilateral modified radical neck dissection as well. Some authors even advocate bilateral modified radical neck dissection initially or very extensive “microdissection.”⁴² Because of technical issues and an unclear influence on prognosis, this approach has not met with widespread acceptance.

TABLE 75.2

CLASSIFICATION

DISEASE PHENOTYPES RELATED TO MUTATION OF THE RET PROTO-ONCOGENE

■ PHENOTYPE	■ GENETIC DEFECT	■ CLINICAL FEATURES	■ PREVALENCE (%)
MEN 2A (60%)	Germline mutations in cysteine codons of extracellular and transmembrane domains of RET	Medullary thyroid carcinoma Pheochromocytoma Hyperparathyroidism	100 10–60 5–20
MEN 2B (5%)	Germline activating mutation in tyrosine kinase domain or RET	Medullary thyroid carcinoma Pheochromocytoma Marfanoid habitus Mucosal neuromas (gut) and ganglioneuromatosis	100 50 100 100
FMTC (35%)	Germline mutations in cysteine codons of extracellular or transmembrane domains of RET	Medullary thyroid carcinoma	100

FMTC, familial medullary thyroid carcinoma; MEN, multiple endocrine neoplasia.

It is common for patients to have persistent hypercalcemia even after an extensive initial operation. Most patients have a subsequent indolent course, although some patients will progress more rapidly. Experience with remedial neck dissections in an attempt to render the patient normocalcemic has generally been disappointing and requires an appropriate search for distant metastases before operation is planned. This may include extensive imaging tests such as CT scanning, ultrasound, somatostatin receptor scintigraphy scanning, selective venous sampling for calcitonin levels, and laparoscopy to investigate for hepatic metastases.⁴³ For most patients, the strategy of observation by clinical examination, biochemical markers, and imaging tests is adopted with interval reassessment for resectable regional and metastatic disease. When this is detected, especially if it is in a location whereby ongoing growth could cause significant morbidity (e.g., tracheoesophageal groove), resection can be offered. Hepatic resections for diffuse metastatic disease are inadequate, whereas such an operation may be considered for isolated bulky metastatic deposits. Chemotherapy has largely been ineffective, although trials with selective and nonselective tyrosine kinase-inhibiting drugs are ongoing. Progress has been limited by difficulty in establishing the desired degree of RET inhibition. Somatostatin analogues can be helpful in slowing the growth of the tumor in some patients. External beam radiotherapy may be useful for locoregional tumor control, especially in those patients with evidence of locally aggressive tumor behavior⁴⁴; however, this should not be employed until appropriate surgical options are exhausted.

Provocative testing (e.g., pentagastrin or calcium-stimulated calcitonin levels) was until recently a standard screening maneuver to identify patients with heritable forms of MTC. Now, these familial forms of MTC, or at least the risk of developing the manifestations, may be diagnosed with the aid of genetic testing for mutations in the RET proto-oncogene. The best use of such testing is to identify the specific mutation in affected family members, which then guides testing of the progeny. When other kindred members with the mutation are identified, thyroidectomy may be performed before malignancy develops. Worldwide cooperation has allowed for genotype/phenotype correlation based on youngest age of diagnosis according to the specific mutation identified. Recommendations for the age of prophylactic thyroidectomy to be performed are based on this information (Table 75.3). The thyroid resection must be absolutely complete because the region of thyroid that remains after a near-total or subtotal thyroidectomy is the region that is most densely populated with C

cells. If hyperparathyroidism is present and enlarged parathyroid glands are encountered at operation, they should be removed as well. A subtotal parathyroidectomy or total parathyroidectomy and autotransplantation (similar to that which would be considered for MEN 1) are excessive options for the parathyroid disease encountered in MEN 2A and, instead, resection may be guided by morphologic changes in the parathyroid glands. Children identified to have MEN 2B should undergo thyroidectomy and central compartment lymph node dissection as soon as the diagnosis is made, definitely by 2 years of age, but even by 6 months of age as guided by mutation analysis.⁴⁵ If MTC is already evident at the time of diagnosis (as opposed to only C-cell hyperplasia), patients should also undergo ipsilateral neck dissection. There is no consensus about at which age patients confirmed to have FMTC mutation should undergo thyroidectomy, although this decision may be guided by the specifics of the family history.

Anaplastic Carcinoma. Although it formerly accounted for a larger fraction of thyroid malignancies, undifferentiated or anaplastic cancer now accounts for just 1% to 2% of thyroid cancers. Most commonly, this occurs in elderly patients with a long-standing history of a goiter. There is significant evidence to infer that most anaplastic thyroid cancers of the spindle cell or giant cell type arise from transformation of DTC, especially follicular and papillary carcinoma. Anaplastic thyroid carcinoma is one of the most aggressive and rapidly

lethal malignancies known. Nearly all are too far advanced at the time of diagnosis to be adequately treated by currently available therapies. The diagnosis may be made by appropriate clinical suspicion (rapidly growing firm thyroid mass) and FNA. If not, excisional biopsy at operation may be required. If airway compromise is present or impending, operation may include debulking and tracheostomy. Occasionally, a small anaplastic cancer is found that is confined to the thyroid or is minimally invasive to surrounding tissues (e.g., trachea). Especially in a young patient, aggressive resection may be legitimately considered. The long-term prognosis for these patients, however, is usually limited by metastatic disease, which may not be apparent at diagnosis. Adjuvant or primary palliative therapy consisting of chemotherapy and external beam radiotherapy is frequently employed. It is common to see a measurable response early in therapy, but eventual tumor progression is typical. Unfortunately, the overall impact is often very limited, so no single regimen has become a standardized approach. Although doxorubicin, Taxol, and other drugs have been tried, doxorubicin and cisplatin are more frequently used. Radiation therapy is often given in combination with chemotherapy by using a hyperfractionated routine such as two daily fractions, 5 days per week, until a total of 40 Gy is delivered to the cervical compartments and superior mediastinum.⁴⁶ Most often, chemotherapy and radiotherapy follow an operation performed for diagnosis or airway protection, but such a regimen may also be used occasionally as neoadjuvant therapy before an attempt at resection is undertaken.

7 Thyroid Lymphoma. Primary thyroid lymphomas are rare tumors that account for fewer than 5% of thyroid malignancies. The majority are classified as non-Hodgkin lymphomas of B-cell origin. Nearly all arise from within a background of Hashimoto thyroiditis. Most patients present with a rapidly enlarging thyroid mass and compressive symptoms (e.g., dyspnea, dysphagia, choking, pain) and have a history of hypothyroidism (Fig. 75.7A, B). Because the rarity of the diagnosis has limited the number of prospective randomized trials that have evaluated the optimal treatment for thyroid lymphomas, most recommendations are based solely on retrospective case series. Patients with diffuse large B-cell lymphoma are generally treated with combination chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]) followed by radiation therapy for stage IE or IIE disease.⁴⁷ In those with pure marginal zone B-cell lymphoma, some have advocated for single-modality therapy (surgery or

radiation) given its more indolent behavior, but this still remains controversial and would be limited to those with stage IE nonbulky disease.⁴⁸ There are limited reports on the use of immunochemotherapy (rituximab + CHOP) for thyroid non-Hodgkin lymphoma (NHL), but given the central role that this combination has in the general treatment of many extranodal B-cell NHLs, it may be of value to extrapolate those results when considering therapy for thyroid lymphoma.⁴⁹ The diagnosis must be firmly established. Modern immunophenotypic analysis often allows this to occur with a small amount of tissue obtained by FNA or core needle sampling. Open biopsy is still occasionally required to establish the diagnosis. Substantial surgical resection is often not required, but there is a subset of patients with significant compressive symptoms from respectable tumors who benefit from palliative total or subtotal thyroidectomy.⁵⁰

Metastases to the Thyroid Gland. Isolated metastases from other primary cancers can occur in the thyroid gland, although they are rare. The most common tumor type to do so is renal cell carcinoma, although it can occur from breast, lung, and gastrointestinal carcinomas, as well as melanoma and sarcoma.⁵¹

Staging of Thyroid Malignancy

A number of patient factors have been investigated to predict risk and prognosis for patients with DTC, such as age, gender, tumor size, involvement of lymph nodes, extrathyroidal invasion, tumor grade or histologic features, and completeness of surgical removal. Although there are differences in these systems, in general, they agree that younger patients with smaller tumors have an excellent prognosis with decreased risk of recurrence and death compared with older patients. One early prognostic staging scheme was the AGES system (*age*, histologic grade, extrathyroidal disease [invasion and distant metastases], and tumor size).⁵² Although useful, the scheme was later modified to exclude histologic tumor grade because there was not uniform agreement on DTC grading by pathologists. Another system is the AMES system (*age*, *metastases*, *extrathyroidal invasion*, and *tumor size*), which was originally described for patients with DTC.⁵³ The main criticism of this scheme is that it was defined based on a patient population that included both papillary and follicular thyroid carcinomas, and that there was no accounting for those patients with low-risk versus high-risk FTC. Another

TABLE 75.4 STAGING

TUMOR, NODE, METASTASIS STAGING SYSTEM FOR DIFFERENTIATED THYROID CARCINOMA (PAPILLARY AND FOLLICULAR TYPES)

■ STAGE	■ AGE <45 Y	■ AGE >45 Y
I	T _{any} N _{any} M0	T1 N0 M0
II	T _{any} N _{any} M1	T2 N0 M0
III		T3 N0 M0 or T1–3 N1a M0
IV		T4 N0 M0 or T4a N1a M0 or T1–3 N1b M0
IVB		T4b Any N M0
IVC		T _{any} N _{any} M1

T1, <2 cm; T2, 2–4 cm, >4 cm; T3, >4 cm; T4a, extrathyroidal extension; T4b, invades prevertebral fascia or encases carotid artery or mediastinal vessels.
N0, no nodal involvement; N1, regional nodal metastases; N1a, metastasis to level 6 lymph nodes; N1b, metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes; M0, no distant metastases; M1, distant metastases.

useful prognostic system is the MACIS scoring system (*metastases, age, completeness of resection, extrathyroidal invasion and distant metastases, and tumor size*). This system calculates a composite score based on these factors, then stratifies prognosis in proportion to these scores (<6.00 is very low risk and >8.00 represents greatly increased risk).⁵⁴ The European Organization for Research on Treatment of Cancer (EORTC) based its prognostic scoring system on a multivariate analysis of patients with all types of thyroid malignancies and found that patients with scores of less than 50 had a 5-year survival rate of 95%, whereas those with scores greater than 109 had a 5-year survival rate of 5%.⁵⁵ This system has not been universally adopted for use in DTC because the high-risk, poor-prognostic group contained a large fraction of patients with anaplastic thyroid cancer. Although medullary thyroid carcinoma is considered a differentiated cancer, its biologic behavior differs sufficiently from DTC of follicular cell origin such that its inclusion in this staging system also confounds the prognostic ability somewhat. The familiar TNM system (*tumor size, nodal status, distant metastases*) is also used to provide prognostic information for patients. When used for thyroid cancer, the TNM system has been modified to account for the risk-reducing influence of low patient age (Table 75.4). This system can provide consistency when comparing patients across different series. This system, like all prognostic scoring systems, still has limited utility in guiding initial treatment decisions (e.g., extent of resection) because the important components are unable to be determined until after resection.

Selection of Surgical Procedure

Although thyroidectomy as a primary treatment for DTC is well accepted to be both effective and safe, some controversy persists about the extent of thyroidectomy necessary for low-risk patients. The advantages of total thyroidectomy for all DTCs of follicular cell origin include (a) removal of multifocal intrathyroidal tumors; (b) use of radioiodine to localize and treat small amounts of residual normal thyroid tissue, and more importantly, regional or distant metastases; and (c) after radioiodine

ablation, use of serum thyroglobulin as a sensitive marker of persistent or recurrent disease. If only thyroid lobectomy is performed, radioiodine treatment is usually not optimal because of the increased avidity for RAI of normal thyroid tissue compared to thyroid cancer tissue, and thyroglobulin measurements also lose their utility. After treatment with lobectomy, recurrence develops in the contralateral lobe in about 7% of patients, and half go on to die of thyroid cancer.³⁴ It has been difficult to demonstrate a survival advantage related to extent of thyroidectomy, but a recent study comparing extent of thyroid surgery in patients with PTC showed that patients with PTC greater than 1 cm who underwent total thyroidectomy had a significantly lower risk of recurrence and lower mortality compared with those undergoing thyroid lobectomy.⁵⁶

Lymphadenectomy

Lymphadenectomy for thyroid cancer has been advocated for patients with clinically positive lymph nodes, or those found to have micrometastases by FNA or frozen section. In general, regional lymph node metastases are found in 30% to 40% of patients, although wider ranges have been reported (20% to 90%).^{57–59} A compartment-oriented approach to lymphadenectomy is currently preferred over the previously advocated technique of “berry picking” (removing only grossly positive nodes) if central compartment lymph node dissection and modified radical neck dissection can be performed without significantly increasing morbidity or mortality. Prophylactic central compartment lymph node dissection (CCLND) is an emerging standard in the treatment of papillary thyroid cancer because lymph node involvement is both common and difficult to treat with a remedial operation in the future. Metastatic disease to central compartment lymph nodes can be found in up to 60% of patients with lymph nodes that appear clinically negative. If CCLND is to be added to the routine performance of total thyroidectomy to treat low-risk PTC, it must be assured that the incidence of RLN injury and hypoparathyroidism is not increased, because it can be technically difficult to maintain parathyroid vascularization with a thorough level VI lymphadenectomy. For the first time, in 2006, the American Thyroid Association management guidelines⁵⁹ suggested routine CCLND be considered for patients with papillary thyroid cancer and Hürthle cell cancer if it can be done without increasing morbidity. Properly performed CCLND at the initial operation may diminish the higher risk of damage to nerves or parathyroid glands that is associated with reoperation for a local recurrence. Current evidence suggests that prophylactic CCLND in PTC may decrease disease recurrence with limited data to suggest a survival benefit.⁶⁰ Residual subclinical disease, as indicated by postoperative serum thyroglobulin levels, can be decreased using this strategy.⁶¹

Preoperative Ultrasound

In recent years, US has taken on a more important role for preoperative planning, especially in patients with thyroid cancer. The use of palpation alone to rule out metastases to the central or lateral neck lymph nodes is highly unreliable. Preoperative US should be obtained in all patients with thyroid nodules, and particular attention should be paid to evidence of lymphadenopathy accompanied by concerning imaging appearances (lack of a hilar line, microcalcifications, loss of the typical flattened ovoid shape). A number of institutions have reported detection by US of nonpalpable lymph node metastases in 24% to 39% of patients with papillary thyroid cancer diagnosed by FNA.^{62–64} Even in patients with palpable lymphadenopathy, US can alter the extent of lymphadenectomy in approximately 40% of patients undergoing initial or reoperative surgery.⁶³

Radioiodine Therapy

Radioiodine may be used in two ways after thyroidectomy: low doses are used to demonstrate remaining thyroid tissue or metastatic disease as part of a diagnostic radioiodine scan, whereas higher doses are used for ablation or therapy. The timing of the initial postoperative scan is dictated by the physiology of T_4 and the fact that remnant thyroid tissue or DTC must be stimulated by elevated levels of TSH to take up RAI. Although no precise threshold has been established, a general consensus is held that the TSH should be at least 30 mIU/mL. Traditionally, the rise in TSH level has been achieved by withdrawal of supplemental thyroxine. The half-life of thyroxine is approximately 7 days, so TSH values are significantly elevated 4 to 5 weeks after total thyroidectomy or withdrawal from thyroxine treatment. To minimize the duration of hypothyroid symptoms, patients can be managed with T_3 until 2 weeks prior to scanning, as T_3 has a much shorter half-life (8 to 12 hours) than T_4 .

The use of recombinant human TSH (rhTSH) for ^{131}I uptake scans has become more readily accepted for use in patients with thyroid cancer.⁶⁵ The use of rhTSH avoids the long withdrawal from thyroid hormone replacement and development of troublesome hypothyroid symptoms that occurs over several weeks. It also allows for the opportunity to follow some patients with rhTSH-stimulated serum thyroglobulin levels without performing ^{131}I whole-body scans, especially as ^{131}I whole-body scans are used less frequently and reliance on high-frequency US for early identification of recurrent tumor is now the more favored modality for long-term surveillance of patients with thyroid cancer.

Radioiodine therapy is a rational therapy for DTC because most tumor cells retain the ability to concentrate radioiodine. Additionally, many studies have shown a decreased rate of recurrence and increased disease-specific and overall survival when ^{131}I is used. In 1997, Mazzaferri reported a threefold decrease in the incidence of distant metastatic disease and local tumor recurrence in tumors treated with radioiodine.⁶⁶ In another study, the risk of cancer death was decreased by half (from 16% to 8%) when radioiodine was used after surgery compared with hormone replacement or external radiation alone.⁶⁷ Many clinicians agree that radioiodine is beneficial and well tolerated, but this is certainly not a unanimous opinion.

There are no prospective randomized trials with subgroup analysis to shed light on the dilemma of which patients should receive postoperative radioiodine. The argument is further complicated by the fact that because of the multiple staging and prognostic systems used, comparisons across studies can be difficult. Postoperative RAI is commonly used, even for lower-risk cancers, and thyroid remnant ablation is generally accepted as part of the postoperative treatment of patients who have undergone total or near-total thyroid excision for DTC. It is not entirely evident that using postoperative radioiodine to “clear” a whole-body scan will impact the patient’s recurrence or survival. Perhaps the most appropriate approach is to select patients for postoperative radioiodine therapy based on individual risk assessment.

Several situations exist wherein it is generally agreed that ^{131}I is not beneficial. If the cancer is undifferentiated and does not concentrate radioiodine, ablative or therapeutic efforts will be futile. Intrathyroidal cancers smaller than 1 cm without evidence of metastatic disease are not treated with radioiodine because of their exceptionally low potential for local or distant recurrence. Finally, if only a lobectomy is performed, radioiodine ablation is possible only 25% of the time because of the volume of residual tissue and its avidity for RAI.

Proponents of ^{131}I therapy advocate that all patients who meet the indications for total thyroidectomy should undergo postoperative radioiodine therapy because it should not be

assumed that even negligible amounts of residual thyroid tissue in the neck are tumor-free. Importantly, more than 30% of well-differentiated thyroid cancers will be multifocal, multicentric, or microscopic. In these settings, postoperative remnant thyroid ablation after total thyroidectomy serves to destroy remaining thyroid tissue that may harbor occult microscopic carcinoma. Additionally, it is less confounding to manage and follow a patient without residual thyroid tissue. Without competing normal tissue, visualization of local or distant recurrences on follow-up ^{131}I scanning is possible. If large amounts of thyroid tissue remain after the initial operation, the bright emission of ^{131}I from the residual thyroid will obscure any small areas of local recurrence. Significant residual thyroid tissue will not allow TSH to rise, which can decrease the uptake of ^{131}I during postoperative imaging. Finally, thyroglobulin measurements are the most specific tests for recurrent cancer when no normal thyroid tissue or TgAbs are present and when the Tg level is measured during a period of hypothyroidism—none of which is feasible when a remnant of the thyroid gland remains. It follows, therefore, that only patients with a small cancer (<1 cm) carrying an exceptionally low risk of recurrence should be routinely excluded from consideration of treatment with postoperative radioiodine therapy.

External Beam Radiotherapy

If gross residual disease remains after surgical resection, external radiotherapy may be considered to assist with local tumor control. This is most often a consideration with tumors that invade the tracheoesophageal axis. This occurrence is frequent with poorly differentiated tumors, but it certainly can complicate DTC as well. It has also been considered for patients with extensive lymph node involvement that is characterized by extranodal invasion of metastatic tumor. Bone metastases are rarely treated completely with ^{131}I and, thus, external beam radiotherapy may be effective.⁶⁸ Complications include skin erythema and desquamation and tracheoesophageal mucositis.

Thyroid-stimulating Hormone Suppression

Levothyroxine therapy to suppress TSH levels is commonly recommended for patients with differentiated thyroid carcinoma because TSH is considered a trophic factor for these cancers. The efficacy is inferred from uncontrolled retrospective studies. It is important to individualize the degree of suppression in patients, balancing the risk of recurrence with the risks of subclinical hyperthyroidism (e.g., osteoporosis, cardiac arrhythmias). Many physicians will suppress TSH to undetectable levels (<0.1 mIU/L) in high-risk cancers and less severely (TSH 0.1 to 0.5 mIU/L) in low-risk cancers. If a patient has no evidence of recurrence and has extremely low or undetectable thyroglobulin levels 5 to 10 years after treatment, it may be appropriate to lessen the degree of TSH suppression.

New Horizons and Future Directions

Adjunctive treatment of DTC is dependent on the uptake and concentration of radioiodine by cancerous thyroid tissue. Problematically, it has been reported that as many as 30% of advanced DTC will eventually dedifferentiate, and a portion of these cancers will lose the ability to concentrate radioiodine. Molecular testing of thyroid tumors has become available to help characterize thyroid tumors in pre- and postoperative settings. Several well-documented molecular mutations have been identified in various types of thyroid cancer.⁶⁹ Translocations of

partner genes RET/PTC (1, 2, or 3) are found in up to 40% of papillary carcinomas and are more common in radiation-induced tumors. PAX8-PPAR γ translocations can be identified in up to 40% of follicular carcinomas. Mutation of the BRAF gene in papillary carcinomas is estimated to be present in up to 60% of cases. Sorafenib, a multikinase inhibitor that inhibits serine/threonine kinase Raf (BRAF and c-RAF) and RET, c-kit, and receptor tyrosine kinases (platelet-derived growth factor receptor [PDGFR] and vascular endothelial growth factor receptor [VEGFR]), inhibits tumor growth in anaplastic thyroid carcinoma xenografts with BRAF mutations. In an orthotopic mouse model with PTC harboring a RET/PTC1 mutation, tumor volume was reduced by 94%, and those with BRAF mutations saw a 54% reduction in tumor volume.⁷⁰ Eventually, preoperative molecular testing of fresh or frozen tissue samples (FNA or surgical specimen) will be used to differentiate benign from malignant thyroid nodules. Molecular profiling of thyroid tumors for pre- or postoperative use is a burgeoning field that will likely become commonplace in the next 5 to 10 years and will likely deliver other signaling pathways that could be used for targeted therapeutics.

THYROID SURGERY

After an inauspicious beginning, thyroid surgery has improved remarkably over the last century. Substantial improvements began with the discovery of anesthesia, antisepsis, and improved hemostasis. With these improvements, Albert Theodor Billroth, Theodor Kocher, and William Halsted were able to make substantial technical contributions and lay the foundation of thyroidectomy as a safe and efficacious operation.

Technique

There is little, if any, place for subtotal lobar resections (e.g., nodulectomy) and only an occasional role for isthmusectomy alone. Total thyroid lobectomy is the total extracapsular removal of the lobe and the isthmus while preserving both parathyroid glands, the recurrent laryngeal nerve, and the external branch of the superior laryngeal nerve. Total thyroidectomy is merely a matter of performing a total thyroid lobectomy on the contralateral side during the same operation. Subtotal thyroidectomy is intentional subtotal lobar resection, either unilaterally or bilaterally, and is rarely indicated. Near-total thyroidectomy involves intentionally leaving a minor amount of thyroid tissue to protect the insertion of the RLN and the superior parathyroid gland. When properly performed, it is essentially interchangeable with total thyroidectomy when considering surgical outcomes. For most thyroid procedures, the patient is placed in a supine position or a semi-Fowler position with the arms tucked to the side. A support is placed transversely under the shoulders to aid in extending the neck. This extension must not be too extreme or a significant amount of postoperative pain may occur in the occipitocervical region. After skin preparation, a curvilinear incision is made approximately one to two fingerbreadths above the clavicular heads and not any higher than the level of the cricoid cartilage (Fig. 75.8). If possible, it should be disguised in an existing skin crease. Subplatysmal skin flaps are raised to the level of the thyroid cartilage above, the sternal notch below, and laterally to the sternocleidomastoid muscles. The midline raphe is opened to expose the anterior trachea and the isthmus. The sternohyoid and sternothyroid are then separated from the thyroid lobe. It is this maneuver that leads to division of the thyroid sheath layer as the paraesophageal space is entered. The middle thyroid veins are divided and ligated.

If a pyramidal lobe is present, it is mobilized and divided from the fibrous tissue in any remaining thyroglossal duct

FIGURE 75.8. With the patient's neck extended, the line above indicates the appropriate site of incision for thyroid resection. Camouflage within an existing skin crease is often possible.

tract. The anterior suspensory ligament is divided to mobilize the superior aspect of the isthmus.

Thyroid resection should be performed in a logical orderly sequence as follows: (a) exposure of the thyroid gland, (b) capsular dissection of the superior pole of the thyroid with preservation of the external branch of the superior laryngeal nerve, (c) capsular dissection of the inferior pole of the thyroid lobe with preservation of the inferior parathyroid gland, and (d) capsular dissection of the posterolateral aspect of the thyroid gland with preservation of the superior parathyroid gland and the recurrent laryngeal nerve. Unequivocal identification of the recurrent laryngeal nerve occurs early in the operation and involves progressive exposure superiorly as the dissection continues in order to identify and avoid any extralaryngeal RLN branches. Figure 75.9 indicates the plane of dissection relevant to steps (c) and (d).

Dissection of the superior pole of the thyroid must take place in the plane directly adjacent to the thyroid capsule after the largely avascular space between the pole and the cricothyroid muscle is dissected. To do so more proximally along the superior pole vessels imperils the EBSLN. This nerve is not always identified during thyroidectomy, but it can nearly always be preserved by utilizing this technique. Unequivocal identification of the recurrent laryngeal nerve is mandatory. This is done by many surgeons as direct dissection and exposure in the proximal portion of the RLN before its intersection

FIGURE 75.9. The capsular dissection necessary to preserve well-vascularized parathyroid tissue and a fully functional recurrent laryngeal nerve begins in the area outlined above.

FIGURE 75.10. Boundaries showing high-risk area of central compartment dissection involving the vascular supply to the Superior and inferior parathyroid glands and the recurrent laryngeal nerve. (Adapted from Grodski S, Cornford L, Sywak M, et al. Level VI lymph node dissection for papillary thyroid cancer: Surgical technique. *ANZ J Surg.* 2007;77(4):203–208.)

with the ITA and the ligament of Berry. The safety provided by this maneuver, however, is contingent on continuing the exposure more distally along the nerve as it approaches the cricothyroid space, because it is at this point of genu near the ligament of Berry that the nerve is most vulnerable to iatrogenic injury. Another technique of nerve exposure is provided by the close capsular dissection that takes place when the lobe is retracted anteromedially and the terminal branches of the ITA are divided. As the ligament of Berry is divided, the genu of the nerve is identified and protected. Although visual identification of the RLN remains the “gold standard,” palpation can aid in the process. The nerve is often easy to palpate as a slightly firm linear structure in the tracheoesophageal groove with the lobe retracted anteromedially. Although helpful in guiding early dissection, this technique cannot supplant visual confirmation.

The ability to routinely preserve well-vascularized parathyroid tissue during thyroidectomy is mandatory for surgeons performing these operations. Normal parathyroid tissue is subtle and may be difficult to identify. It can be distinguished from surrounding fat by a slight brownish color and a fine

FIGURE 75.11. The recurrent laryngeal nerve is carefully isolated and dissected free from surrounding tissue in level VI. (Adapted from Grodski S, Cornford L, Sywak M, et al. Level VI lymph node dissection for papillary thyroid cancer: Surgical technique. *ANZ J Surg.* 2007;77(4):203–208.)

FIGURE 75.12. The recurrent laryngeal nerve is carefully repositioned laterally and medially as needed to dissect all fibrofatty and lymphatic tissue from level VI structures. (Adapted from Grodski S, Cornford L, Sywak M, et al. Level VI lymph node dissection for papillary thyroid cancer: Surgical technique. *ANZ J Surg.* 2007;77(4):203–208.)

capillary vascular pattern that is not present in the adjacent fat or thymus.

The central compartment of the neck contains level VI lymph nodes and is bordered by the hyoid bone above, the innominate artery below, and the carotid arteries laterally. Removal of these lymph nodes is a critical component of an operation to treat medullary thyroid carcinoma or in the case of clinically evident lymphadenopathy. To perform a CCLND, the prelaryngeal (Delphian) lymph node(s) adjacent to the pyramidal lobe is excised. After the ipsilateral thyroid lobe is completely resected, the lateral and medial extent of dissection is defined to mobilize the level VI nodes. The superior parathyroid gland must be carefully preserved on its vascular supply as the inferior parathyroid gland is often embedded in the nodal tissue to be removed and must be autotransplanted (Fig. 75.10). The cervical portion of the RLN is completely exposed in a retrograde direction using gentle dissection to divide the overlying fibrofatty and nodal tissue (Fig. 75.11). It is important to remove the nodes located posterior to the RLN and anterior to the prevertebral fascia in addition to the more easily removed nodes located anterior to the RLN (Fig. 75.12). If the nerve is adequately mobilized, this can usually be accomplished en bloc and the nodes may even be left attached to the inferior pole of the thyroid. The block of nodal tissue is then removed down to the level VII nodes at the superior margin of the innominate vein. In order to accomplish this, the cervical thymus must be removed. If unable to be preserved on a branch of the ITA, the inferior parathyroid is autotransplanted into the adjacent sternocleidomastoid muscle (Fig. 75.13).

Minimally invasive techniques for thyroid surgery have evolved significantly in some centers. Attention to detail and knowledge of anatomy is critical when performing operations through very small incisions or even from an entirely endoscopic approach. Patient selection for these approaches is extremely important for success. In general, patients with known Hashimoto thyroiditis, those who have undergone previous surgery within the central neck, or those with large thyroid nodules having a volume greater than 30 mL are usually not considered candidates for minimally invasive approaches for thyroidectomy. Minimally invasive approaches are most often used for patients with indeterminate thyroid nodules undergoing diagnostic thyroid lobectomy. Although more extensive oncologic procedures including CCLND can be performed with these techniques, the most appropriate indications remain benign thyroid disease.⁷¹

FIGURE 75.13. It is not uncommon for the inferior parathyroid gland(s) to become devascularized during dissection of the central compartment. Devascularized parathyroid tissue should be retrieved, minced into 1-mm pieces, and autotransplanted to the ipsilateral sternocleidomastoid muscle. (Adapted from Grodski S, Cornford L, Sywak M, et al. Level VI lymph node dissection for papillary thyroid cancer: Surgical technique. *ANZ J Surg.* 2007;77(4):203–208.)

Three general techniques have been developed. The largest experience exists for minimally invasive video-assisted thyroidectomy (MIVAT), initially developed by Miccoli et al. The MIVAT procedure uses a 5-mm 30-degree laparoscope to aid visualization of dissection planes, nerves, and parathyroid glands while the procedure is performed through an incision of 2.5 cm or smaller. An electro-surgical device is usually used to ligate and divide vessels. The incision may be less painful and more cosmetically pleasing to patients, but average operating time is slightly longer than conventional thyroid surgery.⁷² Slightly different from MIVAT, minimally invasive thyroid surgery (MITS) is done with direct visualization (without video assistance) of critical structures through a small lateral incision (2 to 3 cm). Again, advantages include reduced pain and improved cosmesis with equivalent safety.⁷³ Largely in Asia, there is an evolving experience with a totally endoscopic approach using multiple 5-mm port sites placed either in the axilla or areola of the nipple to avoid cervical incision and allow dissection with laparoscopic equipment.⁷⁴ This places the incision away from the neck in a less noticeable position. Operating time is considerably longer. Morbidity and mortality are not significantly different in experienced hands, but dissemination of this complicated technique has been limited.

Traditional thyroidectomy was developed using standard clamping and tying surgical techniques. Advanced surgical energy instruments for bipolar vessel sealing and ultrasonic scalpels have now been integrated into thyroid resections. The main benefit in thyroidectomy is decreased operative time.^{75–77} Most series indicate that complication rates (hematoma, RLN injury, hypoparathyroidism) are comparable to conventional techniques. Heat generation and lateral thermal spread for a particular instrument are critical to understand and may limit safe application near the RLN and parathyroid glands.

Complications

The risk of death or major disability during thyroidectomy should be diminutive. The key outcomes by which to measure the quality of surgical care, especially relevant to total thyroidectomy, include recurrent laryngeal nerve paralysis

TABLE 75.5 **COMPLICATIONS**

COMPLICATIONS OF TOTAL THYROIDECTOMY

COMPLICATIONS	INCIDENCE (%)
Bleeding	1
Wound infection	1
Thoracic duct leak	1
Hypoparathyroidism	
Transient	9–35
Permanent	0–4
Recurrent laryngeal nerve injury	
Initial operation	
Transient	1–10
Permanent	0–1.4
Reoperation	
Transient	0–22
Permanent	0–13
External branch of superior laryngeal nerve injury	5–28

and hypoparathyroidism (Table 75.5). Although both complications can occur in a self-limited fashion, the persistence or permanence (defined at 6 months after operation) of these complications is a critical measure. For most surgeons, the rate of unintended permanent recurrent laryngeal nerve dysfunction should be no greater than 1% and the rate of permanent hypoparathyroidism should be no greater than 1% to 2%.

Injury to an RLN results in paralysis of the vocal cord it innervates. Depending on the specific branch or combination of branches injured, the cord may remain in a paramedian position (also called cadaveric position) or may remain abducted. If the contralateral cord is able to adduct to the midline or beyond, the patient may have a voice that is not particularly hoarse, but is weak. If the cord is paralyzed in the abducted position, vocal quality is very poor because of the difficulty in approximating the cords during speaking. The patient's cough also has a bovine quality where there is a lack of a sharp, percussive initiation. If both vocal cords are paralyzed, consideration of the specific cord positions is even more critical. If both cords are paralyzed in the abducted position, the patient may have a critically limited ability to phonate. In this situation, the patient may gradually develop some degree of airway obstruction as the cords gradually migrate toward the midline. If both cords are paralyzed in the paramedian position, the airway is critically narrowed. In this situation, stridor is usually apparent very soon after extubation and an emergent procedure (e.g., cricothyroidotomy or tracheostomy) may be required to reestablish a patent airway.

Injury to the EBSLN is both more common and more difficult to detect than injury to the RLN. Because of greater anatomic variations, the EBSLN is at higher risk for injury than the RLN during thyroidectomy.⁷⁸ The symptoms of injury to the EBSLN are usually less noticeable and may be only slightly evident to the patient, but can be devastating in the case of the vocal professional. Symptoms typically include early vocal fatigue, decreased pitch range, and decreased projection ability. Findings on laryngoscopy are subtle and include bowing and inferior displacement of the affected vocal cord and rotation of the posterior glottis toward the injured side. Laryngeal videostroboscopy or percutaneous electromyography of the cricothyroid muscle may be required to detect injury in

subtle cases. Because there is no effective treatment for this condition, prevention is extremely important.

Functional monitoring of EBSLN integrity is feasible but somewhat cumbersome and is not routinely employed. If nerve monitoring is employed, the stimulator probe can also be used to demonstrate the location of the EBSLN by observing a motor response in the ipsilateral cricothyroid muscle. Recurrent laryngeal nerve monitoring is increasingly common in recent thyroid surgery practice. Although the technology has improved to a point that the technique is relatively easy to employ, large studies have failed to detect a major improvement in RLN injury rates (largely related to the low incidence of this complication when thyroidectomy is performed in the proper hands despite the specific technique employed).⁷⁹ Even so, RLN monitoring can be very helpful in facilitating nerve identification and protection during a complex reoperation or initial thyroidectomy for very large goiter or aggressive malignancy, even if it will not materially change the chance of injury.⁸⁰ Since current technologies are essentially nerve integrity monitors, the information provided (loss of action potential at the vocalis muscle) indicates when an injury has or has not occurred and therefore does not indicate when a nerve is under stress from dissection or traction. Therefore, whether or not RLN monitoring is employed, prevention of injury still requires meticulous and precise surgical technique.

The parathyroid glands are at risk during thyroid resection by virtue of the fact that they are often firmly invested within the thyroid sheath or occasionally even within the thyroid capsule. Inferior parathyroid glands are ultimately supplied by the inferior thyroid artery. Superior parathyroid glands are often served by the inferior thyroid artery but may also have contributions from the superior thyroid artery distribution as well. Ligation of the trunk of the ITA must be avoided to preserve blood supply to the parathyroid glands. Every attempt should be made to mobilize the parathyroid glands away from the thyroid tissue being resected while preserving the blood supply. If the gland appears pale or dark and devascularized, the arterial supply is probably compromised. Such a parathyroid gland is unlikely to survive after the operation and should be immediately autotransplanted. This may be done by mincing the gland into 1-mm pieces and inserting or injecting the pieces into well-vascularized skeletal muscle (e.g., sternocleidomastoid or pectoralis).⁸¹ Even during thyroid lobectomy, meticulous technique must be used to preserve parathyroid viability, even though permanent, or even temporary, hypoparathyroidism is unlikely. With total thyroidectomy, careful dissection is even more critical. Temporary hypoparathyroidism is relatively common and is due to mild devascularization or venous congestion of parathyroid glands during mobilization. Approximately 20% to 40% of patients will have mild temporary hypocalcemia beginning about 12 to 36 hours after operation. If symptomatic, it can be treated with oral calcium or occasionally vitamin D supplements (e.g., calcitriol). Severe symptomatic hypocalcemia can be treated with intravenous calcium gluconate. Temporary hypoparathyroidism complicating thyroidectomy usually resolves over days to weeks, although occasionally it may take months to do so. Hypoparathyroidism that persists longer than 6 months is usually destined to be permanent. The transient hypocalcemia after total thyroidectomy may be worse in the patient with Graves disease because of the increased bone turnover observed with hyperthyroidism; however, recovery is expected and the incidence of permanent hypoparathyroidism should be no higher than in euthyroid patients.

Regardless of the specific extent or technique of thyroidectomy, these complications can largely be avoided or ameliorated by delicate and deliberate surgical technique. A thorough understanding of the function and anatomy, both normal and abnormal, of the thyroid gland, and of the rationale behind various treatment options, is critical to ensure the best outcomes for our patients.

CHAPTER 76 ■ PARATHYROID GLANDS

GERARD M. DOHERTY

KEY POINTS

- 1 The normal parathyroid glands are flat, ovoid, and red-brown to yellow. Their dimensions are 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm, and they weigh between 30 and 50 mg each.
- 2 Parathyroid hormone is the single most important hormonal regulator of calcium and phosphate metabolism in humans with direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D.
- 3 The demonstration of an elevated plasma parathyroid hormone concentration alone does not establish the diagnosis of hyperparathyroidism; with a simultaneous elevated serum calcium level, this finding is virtually diagnostic.
- 4 A large proportion of patients with the diagnosis of hyperparathyroidism are minimally symptomatic or asymptomatic and the appropriate treatment for these patients remains controversial.
- 5 It is routinely possible to identify abnormal parathyroid glands prior to operation for most patients, allowing the surgeon to know where to start the exploration; intraoperative parathyroid hormone measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation.

ANATOMY

- 1 Typically, a person has four parathyroid glands—two superior and two inferior (Fig. 76.1).¹ The normal parathyroid glands are flat, ovoid, and red-brown to yellow. They measure 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm and weigh between 30 and 50 mg each. The lower glands are usually larger than the upper glands. The superior glands are most often embedded in the fat on the upper posterior surface of the thyroid lobe near the site where the recurrent laryngeal nerve enters the larynx. The inferior glands are usually more ventral and lie close to or within the portion of the thymus gland that extends from the inferior pole of the thyroid gland into the chest. Although this anatomy is fairly consistent, substantial variations from the usual can occur, and it is essential that the surgeon have a thorough understanding of these anatomic variations.

Variations in parathyroid gland anatomy are primarily caused by differences in patterns of embryogenesis. During the fourth and fifth weeks of fetal development, a series of four pharyngeal pouches develop (Fig. 76.2). The superior parathyroid gland arises from the fourth pharyngeal pouch in conjunction with the lateral thyroid, and the inferior gland arises from the third pouch along with the thymus. The derivatives of each pouch then migrate together so that the superior parathyroid gland usually remains in close association with the upper pole of the thyroid, although it may occasionally be loosely attached by a long vascular pedicle, migrating caudad along the esophagus into the posterior mediastinum. Occasionally, a gland may be totally embedded in the thyroid parenchyma. The inferior parathyroid gland descends with the thymus, but this migration is extremely variable. Inferior glands can be found anywhere from the pharynx to the mediastinum. Regardless of their location, they usually adhere to the thymus or are within the thyrothymic ligament. Supernumerary glands can be identified in up to 15% of patients, most often in association with the thymus. Autopsy studies suggest that four parathyroid glands are virtually always present.

The arterial supply to both the superior and inferior parathyroid glands is usually from the inferior thyroid artery, although it may arise from the superior thyroid or thyroidea ima arteries or from the rich anastomosis of vessels supplying

the larynx, trachea, and esophagus. A mediastinal parathyroid gland that descended during embryonic development usually receives its blood supply from either the internal mammary artery or small arteries within the thymus; however, an enlarged parathyroid gland that grows into the mediastinum usually carries with it the corresponding branch of the inferior thyroid artery. The inferior, middle, and superior thyroid veins, which drain the parathyroid glands, empty into the internal jugular vein or the innominate vein.

Histologically, the normal adult parathyroid gland is about half parenchyma and half stroma, including fat cells (Fig. 76.3). In children, the gland is almost entirely composed of parenchymal chief cells. Beginning at puberty, adipocytes appear and, with age, occupy an increasing proportion of the gland. Also with increasing age, acidophilic, mitochondria-rich oxyphil cells are present in increasing numbers and are intermixed with the glycogen-laden, polygonal, water-clear cells. The functional significance of the various cell types remains unclear, although the water-clear cells and oxyphil cells are probably derived from the chief cells and secrete parathyroid hormone (PTH).

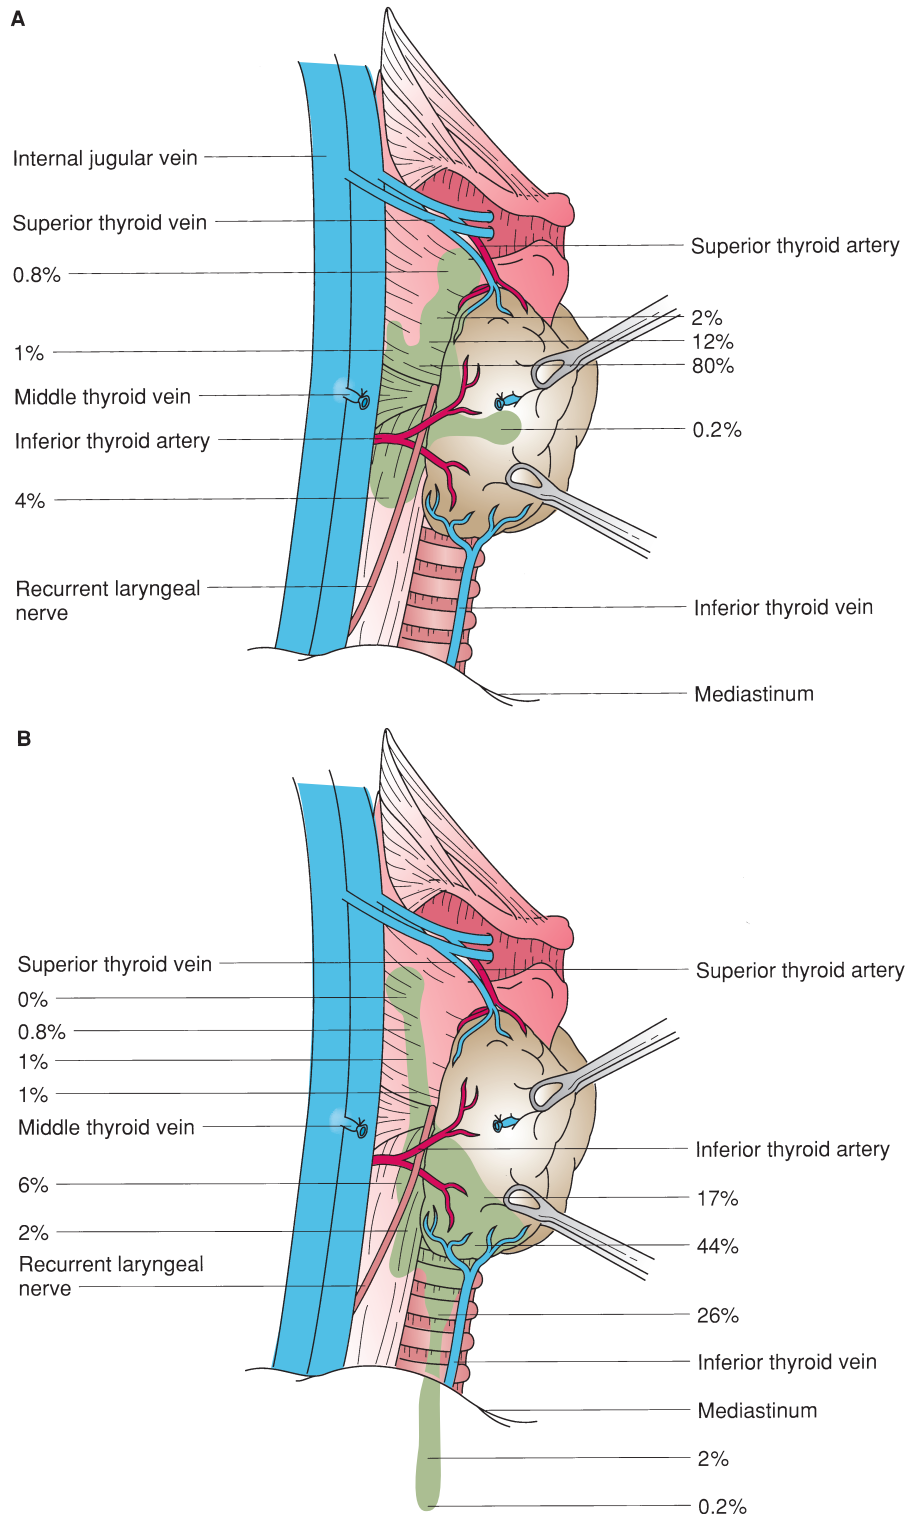

PHYSIOLOGY

The primary physiologic role of the parathyroid gland is the endocrine regulation of calcium and phosphate metabolism. Average daily exchanges of these ions from the gastrointestinal tract, bone, and kidney are shown in Fig. 76.4.

Calcium

Calcium ion plays a critical role in all biologic systems. It participates in enzymatic reactions and is a mediator in hormone metabolism. Calcium is intimately involved in the physiology of neurotransmission, muscle contraction, and blood coagulation. It is the major cation in bone and teeth. It represents about 2% of the average body weight, and almost all calcium is contained in the skeleton. The normal range of serum calcium is 9 to 10.5 mg/dL (4.5 to 5.2 mEq/L), and the daily variation in a

FIGURE 76.1. Schematic illustration of the location of the superior (A) and inferior (B) parathyroid glands from 503 autopsy studies. The more common locations are indicated by the shaded areas. The numbers represent the percentage of glands found at each location. Typically, the glands were posterolateral to the thyroid and above or below the junction of the inferior thyroid artery with the recurrent laryngeal nerve. (After Akerstrom G, Malmaers J, Bergstrom R. Surgical anatomy of human parathyroid glands. *Surgery* 1984;95:14.)

normal person is generally less than 10%. About half of the total serum calcium is in an ionized, biologically active form; 40% is bound to serum protein, mainly albumin, and 10% forms compounds with organic ions, such as citrate. The total serum calcium concentration is a function of the serum protein content, and because hydrogen ion competes with calcium for the same binding sites on albumin, the body fluid pH is important. In general, for every change of 1 g/dL in the serum albumin level, a direct alteration of 0.8 mg/dL occurs in the serum calcium concentration. Almost all the physiologically impor-

tant activity of calcium is represented by the unbound, or free, fraction.

Calcium is absorbed in its inorganic form from the duodenum and proximal jejunum. The rate of absorption is precisely regulated according to body calcium status. The calcium in the extracellular fluid is constantly being exchanged with that in the intracellular fluid, the exchangeable bone, and the glomerular filtrate. Calcium reabsorption by the kidney is closely related to that of sodium, and about 99% of the filtered load is reabsorbed under normal conditions.

FIGURE 76.2. A: Pharyngeal arches in a 5-week embryo. The corresponding pouches extend from within the pharynx into each arch. B: Schematic representation of the differentiating epithelium of the respective pharyngeal pouches. (After Langman J. *Medical Embryology and Human Development: Normal and Abnormal*. Baltimore, MD: Williams & Wilkins; 1975:262.)

FIGURE 76.3. A normal adult parathyroid is composed of about half parenchyma and half fat ($\times 150$).

Phosphate

Phosphate anion is also an integral component of most biologic systems. It is critical to the pathways of glycolysis and is the functional group for a number of high-energy transfer compounds, including adenosine triphosphate. It is also the major anion in crystalline bone. Normal levels of plasma phosphate range from 2.5 to 4.3 mg/dL, and the level varies inversely with the serum level of calcium. The relation is such that the product of plasma calcium and phosphate is relatively constant ranging between 30 and 40 (with calcium and phosphate both expressed in mg/dL). When the product is above this level, the potential for the precipitation of calcium phosphate in body tissues increases.

In contrast to the percentage of calcium absorbed, the percentage of phosphate absorbed from the diet is relatively constant, and excretion usually provides the major mechanisms for regulating phosphate balance (Fig. 76.4). Unlike stores of calcium, the readily exchangeable soft tissue stores of phosphate, such as those in muscle, are large.

FIGURE 76.4. Average daily calcium and phosphate turnover in humans. (After Aurbach GD, Marx SJ, Spiegel AM, et al. Parathyroid hormone, calcitonin, and the calciferols. In: Wilson JD, Foster DW, eds. *Textbook of Endocrinology*, 7th ed. Philadelphia, PA: WB Saunders; 1985:1144, with permission.)

Regulation of Calcium and Phosphate Metabolism

The maintenance of calcium and phosphate homeostasis depends on major contributions from three organ systems—the gastrointestinal tract, the skeleton, and the kidneys—with minor contributions from the skin and liver.² The primary hormonal regulators of this metabolism are PTH, vitamin D, and calcitonin. The actions of each of these hormones in the organs are summarized in Table 76.1.

2 Parathyroid Hormone. PTH is the single most important hormonal regulator of calcium and phosphate metabolism in humans. It has direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D. In target tissues, PTH binds first to membrane receptors, activating adenyl cyclase to generate cyclic adenosine

monophosphate (cAMP), which regulates other intracellular enzymes.

In bone, the effects of PTH are complex, stimulating both resorption and the formation of new bone. However, sustained elevations of PTH stimulate osteoclasts and inhibit osteoblasts. Osteocytes, in the matrix of cortical bone, may also act to reabsorb matrix in response to PTH, a process referred to as *osteocytic osteolysis*. Calcium and phosphate mobilization in response to PTH occurs in two phases. Initially, mineral is mobilized from areas of rapid equilibrium. This phase is followed by a more sustained release mediated by newly synthesized lysosomal and hydrolytic enzymes. In the kidney, PTH increases the reabsorption of extracellular fluid calcium at any given concentration, although excess secretion, because of hypercalcemia, increases the net daily amount of urinary calcium excretion. Reabsorption in the proximal tubule and loop of Henle is linked with sodium transport such that factors that alter sodium transport concomitantly alter calcium reabsorption. In

TABLE 76.1

HORMONAL REGULATION OF CALCIUM AND PHOSPHATE METABOLISM

■ LOCATION	■ PARATHYROID HORMONE	■ VITAMIN D	■ CALCITONIN
Gastrointestinal tract	No direct effect	Stimulates calcium and phosphate absorption	No direct effect
Skeleton	Stimulates calcium and phosphate resorption	Stimulates calcium and phosphate resorption	Inhibits calcium and phosphate resorption
Kidneys	Stimulates calcium resorption	No direct effect	Inhibits calcium and phosphate resorption

FIGURE 76.5. The parathyroid gland produces a precursor of parathyroid hormone (PTH), prepro-PTH, that is sequentially cleaved to pro-PTH and PTH. PTH secretion is controlled by the extracellular fluid calcium concentration. (After Klee GG, Kao PC, Heath H. Hypercalcemia. *Endocrinol Metab Clin North Am* 1988;17:573.)

contrast, reabsorption in the distal nephron is independent of sodium and directly influenced by PTH. PTH also increases phosphate excretion. This action is accompanied by enhanced bicarbonate secretion. PTH probably has only indirect effects on the gastrointestinal tract, by stimulating the hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in the kidney.

PTH is synthesized initially as a precursor, preproPTH, which is sequentially cleaved in the parathyroid gland to proPTH and then to PTH (Fig. 76.5). Secretion of this 84-amino-acid molecule is controlled by a negative feedback loop with extracellular fluid calcium. Most PTH is secreted in this form and then cleaved in the liver into N- and C-terminal fragments. The N-terminus contains most of the biologic activity and is rapidly degraded by the liver, whereas the inactive C-terminus is slowly metabolized by the kidney.

Vitamin D. Vitamin D acts at two major sites. It increases intestinal absorption of calcium and phosphate. In addition, in the skeleton, it promotes mineralization and enhances PTH-mediated mobilization of calcium and phosphate. It probably has no direct effect on the kidney.

Vitamin D₃, or cholecalciferol, is produced normally by the action of sunlight on 7-dehydrocholesterol in the skin (Fig. 76.6). It is then hydroxylated in the liver (25 position) and kidney (1 position) to form the active 1,25-dihydroxyvitamin D₃ (calcitriol). Vitamin D₂ is normally present in yeast and fungi but not in humans. It is the major pharmacologic source of vitamin D. Pharmaceutical preparations include vitamin D₂ (ergocalciferol), 25-hydroxycholecalciferol (calcifediol), and 1,25-dihydroxycholecalciferol (calcitriol). 1-Hydroxycholecalciferol and dihydrotachysterol are synthetic preparations that require only 25-hydroxylation for activity and so are useful for supplementation in patients with renal failure, who lack the 1-hydroxylase.

Calcitonin. Calcitonin is a 32-amino-acid protein produced by the parafollicular C (calcitonin) cells of the thyroid. The C cells are embryologically derived from the neural crest and, in lower animals, are found in the ultimobranchial bodies, which are glandular structures derived from the lowest branchial pouch. In humans, these structures are incorporated into the superior and lateral aspects of the thyroid lobes.

Total thyroidectomy, with removal of all the C cells, is well tolerated. Calcitonin is not essential for the normal control of calcium metabolism in adult humans. It does inhibit bone resorption and can produce hypocalcemia in experimental animals. It also increases urinary calcium and phosphate excretion. These effects are mediated primarily through cAMP. Several secretagogues for calcitonin have been identified, including catecholamines, gastrin, and cholecystokinin, but the most potent appear to be calcium and pentagastrin. Exogenously administered calcitonin can be useful pharmacologically to reduce serum calcium levels.

Mineral Homeostasis. Under normal conditions, serum calcium and phosphate levels vary minimally during the course of the day. Regulation occurs primarily through PTH but also through a series of feedback loops involving vitamin D and calcitonin (Fig. 76.7). A fall in serum ionized calcium increases PTH secretion and stimulates the production of 1,25-dihydroxyvitamin D₃. Conversely, increases in serum calcium inhibit PTH secretion and the formation of active calciferol.

Pathophysiology

Diseases of the parathyroid glands present almost exclusively as disorders of calcium metabolism. Hypercalcemia is the most common manifestation, and in the patient who presents with an elevated serum calcium level, the differential diagnosis can be complex. A thorough understanding of both hypercalcemia and hypocalcemia is essential for the successful treatment of patients undergoing parathyroid surgery. Primary disorders of plasma phosphate are not usually related to surgical disease and are not discussed in detail here.

HYPERCALCEMIA

Hypercalcemia is a relatively common clinical problem.^{3,4} In the general population and in hospital outpatients, the incidence is between 0.1% and 0.5%. Most patients in this group have primary hyperparathyroidism. In contrast, hypercalcemia is identified in almost 5% of hospitalized patients, and nearly two thirds of them have a malignancy.

FIGURE 76.6. Schematic illustration of the synthesis of vitamin D₃. Ergosterol, 1- α -hydroxyvitamin D₃, and dihydrotachysterol are synthetic preparations of vitamin D. (After Klee GG, Kao PC, Heath H. Hypercalcemia. *Endocrinol Metab Clin North Am* 1988;17:573.)

Clinical Manifestations

The symptoms of hypercalcemia are varied and nonspecific (Table 76.2). Severity is a function of both the magnitude and rapidity of onset of the hypercalcemia. Many of the manifestations are subtle and are evident only in retrospect, after the patient has been successfully treated for the cause of the elevated calcium. Specific symptoms and diagnostic tests are addressed in more detail in the section on hyperparathyroidism.

Differential Diagnosis

Although the diagnosis of primary hyperparathyroidism can, after appropriate investigation, be established with confidence in most patients, all causes of hypercalcemia must be considered

and excluded. The multiple causes of hypercalcemia are listed in Table 76.3.

Etiology

Hyperparathyroidism. The diagnosis of hyperparathyroidism is discussed in detail later. Patients typically have elevated plasma concentrations of calcium and PTH, increased urinary excretion of calcium, and a low plasma concentration of phosphate.

Malignancy. Generally, patients with hypercalcemia and malignancy (humoral hypercalcemia of malignancy) can be classified into two groups.⁵⁻⁷ Patients with solid tumors, such as lung carcinoma (25% of all cases of humoral hypercalcemia

FIGURE 76.7. Feedback loops involved in the regulation of serum calcium and phosphorus. CT, calcitonin; PTH, parathyroid hormone.

of malignancy); breast carcinoma (20%); squamous cell carcinoma of the head, neck, esophagus, or female genital tract (19%); or renal cell cancer (8%), account for three fourths of all cases. Humoral hypercalcemia of malignancy in this setting generally appears late in the disease, with nearly all patients having known, or readily evident, malignancy. These patients have elevated levels of serum calcium, low levels of serum phosphorus, and elevated levels of urinary cAMP, consistent with increased PTH activity but normal or low serum PTH levels. The hypercalcemia is now known to be caused by PTH-related protein secreted by the tumor, rather than by the bony metastases that many of these patients have because of the advanced nature of their cancers. In the second group, accounting for one fourth of cases, are patients with hematologic malignancies, such as multiple myeloma, certain lymphomas and leukemias, and a subset of the patients with breast cancer. These patients have elevated levels of serum calcium, but in contrast to most patients with solid tumors and humoral hypercalcemia of malignancy, they have elevated levels of serum phosphate and low levels of urinary cAMP. These patients always have lytic bony lesions and histologically demonstrate increased

osteoclast bone resorption adjacent to tumor cells. This osteoclast-activating activity is an effect of cytokines, mainly interleukin-1 β and tumor necrosis factor- β (lymphotoxin). These cytokines promote local net bone resorption and thus produce hypercalcemia and hyperphosphatemia.

Vitamin D and Vitamin A Intoxication. When administered in excess, vitamins A and D can produce hypercalcemia. Affected patients tend to have normal or elevated serum phosphate levels associated with a low PTH level. Metastatic calcification may occur.

Thiazide Diuretics. Thiazides may increase serum calcium levels to a mild degree, primarily through hemoconcentration and decreased renal excretion. Serum phosphate may also be depressed. It often takes several weeks for the hypercalcemia to resolve after the medication is discontinued.

Hyperthyroidism. Hyperthyroidism is associated with increased bone resorption. Often, the plasma PTH is low, and a history of other thyrotoxic symptoms can be elicited. The hypercalcemia usually resolves as the patient becomes euthyroid.

Milk-Alkali Syndrome. Typically, the milk-alkali syndrome occurs in patients with peptic ulcers who consume large quantities of milk and absorbable antacids. Usually, some degree of renal failure is present. PTH levels are low. This syndrome has become much less common with the increased use of nonabsorbable antacids, histamine 2-receptor antagonists, and proton pump inhibitors as therapy for peptic ulcer disease.

Sarcoidosis and Other Granulomatous Diseases. These syndromes are associated with hypersensitivity to vitamin D. The granulomas can convert inactive vitamin D to its active form. Patients have elevated plasma globulins and low PTH levels. The administration of large doses of corticosteroids for 10 days usually reduces the hypercalcemia. Biopsy of lymph nodes or the liver may confirm the diagnosis.

Familial Hypocalciuric Hypercalcemia. This disease is an asymptomatic, autosomal dominant condition characterized by mild to moderate hypercalcemia, hypocalciuria, and normal or only slightly elevated PTH levels. It develops in people heterozygous for a mutation in the calcium-sensing receptor.^{8,9} The mutation causes an increase in the set point for extracellular calcium concentration, so that the “normal” calcium level is higher in these people than in the normal population. No treatment is necessary, although people with this disease should receive genetic counseling. Neonatal severe hyperparathyroidism, which can be fatal, develops in children homozygous for mutations in this receptor. Treatment for neonates with this disease is controversial, but they appear to benefit from early surgical management.

Immobilization. Immobilization produces hypercalcemia by increasing the ratio of bone resorption to bone formation. These patients can usually be distinguished by history, although on laboratory evaluation they have elevated serum levels of calcium and phosphate and a decreased serum concentration of PTH. Often, hypercalciuria is present, which may lead to the development of renal stones. Treatment is early mobilization and forced diuresis.

Other Causes. A variety of other diseases may produce hypercalcemia. For example, Paget disease (osteitis deformans) typically causes mild elevations in serum calcium. Paget disease can be diagnosed on the basis of the characteristic radiographic lesion. Adrenal insufficiency may be associated with hypercalcemia, although the symptoms are typically those of the primary abnormality. Lithium therapy appears to produce hypercalcemia by altering the parathyroid set point for inhibition by

calcium and, over long courses of therapy, may also be associated with hyperparathyroidism. Idiopathic hypercalcemia of infancy is a rare disorder that is probably the result of hypersensitivity to vitamin D. It occurs in infants with mental retardation and is satisfactorily treated with glucocorticoids. Other causes include aluminum-induced renal osteomalacia and a host of analytic errors related to improper specimen collection with prolonged tourniquet times, tube contamination, and instrument drift.

Medical Treatment

Although the choice of therapy is tailored to the cause of the hypercalcemia, several general measures can prove effective.^{4,10,11}

For the patient with mild hypercalcemia, a trial of a decrease in dietary calcium is indicated. A reduction in intake of milk and other dairy products is suggested, along with discontinuation of thiazide diuretics and vitamin D preparations. Mobilization prevents bone demineralization.

Patients with more marked hypercalcemia or severe symptoms should be admitted to the hospital for treatment, with careful observation and monitoring. In the patient with severe hyperparathyroidism, although the definitive therapy is surgical, it is unwise to proceed with neck exploration until the calcium has been reduced to near-normal levels. The mainstay of therapy is intravenous hydration, preferably with normal saline solution in sufficient quantities to maintain the urine output above 100 mL/h. These patients are often dehydrated before therapy, and fluid can be administered intravenously at a rate of 200 mL/h. Caution must be exercised in older patients, whose cardiac reserve may be marginal. This therapy exploits the parallel handling of calcium and sodium by the kidneys. The diuretic furosemide also increases sodium and calcium excretion but should not be used until the patient is well hydrated.

The endpoints of therapy are a decrease in the serum calcium level and a reduction of symptoms. Diuresis with saline solution is usually effective when the hypercalcemia results from hyperparathyroidism or a benign cause. In contrast, the hypercalcemia of malignancy may produce severe symptoms associated with extremely high serum calcium levels that are difficult to control. In this setting, a variety of other measures may be considered (Table 76.4). Some of the agents used to treat hypercalcemia cause significant toxicity, and close patient monitoring is required during treatment. Calcitonin is a fairly weak hypocalcemic agent, but it acts rapidly and is associated with less toxicity than many of the other drugs.¹¹ Salmon calcitonin is the most potent preparation. Treatment with glucocorticoids is particularly efficacious in patients with sarcoidosis and other granulomatous diseases. Plicamycin has proved useful in patients with hypercalcemia of malignancy, but it causes a cumulative toxicity (thrombocytopenia, hepatotoxicity, and nephrotoxicity). Bisphosphonates inhibit osteoclast activity directly. These agents are administered orally or parenterally and are particularly efficacious, although long-term use may be associated with significant osteomalacia.^{5,12} Prostaglandin synthetase inhibitors were initially considered useful, but their efficacy has proved to be limited. Intravenous phosphates and chelating agents have largely been abandoned because of their severe toxicity; however, oral phosphates may be beneficial in patients requiring prolonged therapy.

HYPOCALCEMIA

Hypocalcemia can occur as a consequence of various acquired and hereditary diseases.^{13,14} Generally, these disorders produce a deficiency or defect in the action of either PTH or vitamin D. It is most commonly a significant clinical problem after neck operation for thyroid disease. Chronic vitamin D deficiency is associated with compensatory PTH excess. The end result is rickets in children or osteomalacia in adults.

TABLE 76.4

TREATMENT

TREATMENT OF HYPERCALCEMIA

Therapy of Primary Disease

- Tumor resection (hypercalcemia of malignancy)
- Parathyroidectomy (primary hyperparathyroidism)

Expansion of Extracellular Volume

- Infusion of saline solution
- Enhancement of urinary calcium excretion
- Extracellular volume expansion
- Loop diuretics (furosemide and ethacrynic acid)

Inhibition of Bone Resorption

- Calcitonin
- Glucocorticoids
- Plicamycin (mithramycin)
- Bisphosphonates
- Gallium nitrate

Reduction of Intestinal Calcium Absorption

- Low-calcium diet
- Glucocorticoids

Other Treatments

- Dialysis
- Mobilization
- Oral phosphate
- Estrogens or progestogens (postmenopausal women with primary hyperparathyroidism)
- Chloroquine (sarcoidosis)

Modified from Attie MF. Treatment of hypercalcemia. *Endocrinol Metab Clin North Am* 1989;18:802.

Clinical Features

The major signs and symptoms of hypocalcemia are a direct consequence of the reduction in plasma levels of ionized calcium, which increases neuromuscular excitability (Table 76.5).

TABLE 76.5

DIAGNOSIS

CLINICAL FEATURES OF HYPOCALCEMIA

Neurologic

- Circumoral paresthesia
- Light-headedness
- Depression
- Anxiety
- Confusion
- Chvostek sign
- Trousseau sign
- Irritability
- Laryngeal spasm
- Seizures

Musculoskeletal

- Tetany
- Cramps
- Involuntary twitching
- Osteomalacia

Cardiovascular

- Electrocardiogram changes (prolonged QT interval, T-wave peaking)
- Arrhythmia
- Tachycardia, hypotension

Other Features

- Lenticular cataracts

TABLE 76.6 ETIOLOGY**CAUSES OF HYPOCALCEMIA**

- Hypoparathyroidism
- Vitamin D deficiency
- Pseudohypoparathyroidism
- Hypomagnesemia
- Malabsorption
- Pancreatitis
- Hypoalbuminemia
- Chelation of calcium
- Osteoblastic metastases
- Toxic shock syndrome
- Hyperphosphatemia

The earliest clinical manifestations are numbness and tingling in the circumoral area, fingers, and toes. Mental symptoms are also common. Patients become anxious, depressed, and occasionally confused. Tetany may develop, characterized by carpopedal spasm, tonic-clonic convulsions, and laryngeal stridor. The magnitude of symptoms at any given plasma concentration of ionized calcium varies from patient to patient. On physical examination, contraction of the facial muscles is elicited by tapping anterior to the ear, over the facial nerve (Chvostek sign), although this sign may be present in 10% of normal patients. Trousseau sign is elicited by occluding blood flow to the forearm for 3 minutes. The development of carpal spasm indicates hypocalcemia, although the test is unpleasant and clinically impractical.

Etiology

Some of the causes of hypocalcemia are listed in Table 76.6. The most common cause of hypocalcemia by far is excision of or damage to the parathyroid glands during thyroid surgery.

Postoperative Hypoparathyroidism. Postoperative hypoparathyroidism commonly develops after total thyroidectomy.^{14–16} Most patients undergoing operation on the thyroid experience some alteration in serum calcium, although they often are asymptomatic; the low calcium probably represents contusion or temporary alteration of the blood supply to the parathyroid glands. The hypocalcemia is usually transient and is not treated unless significant symptoms develop. Occasionally, in hyperparathyroid patients who have parathyroidectomy and significant bone disease, a marked skeletal deposition of calcium and symptomatic hypocalcemia occurs, so-called *bone hunger*. The plasma calcium usually reaches its nadir at 48 to 72 hours after surgery and then slowly returns to normal within several days. These patients may require calcium and vitamin D therapy for weeks or months after parathyroidectomy.

Idiopathic Hypoparathyroidism. A less common form of hypoparathyroidism is idiopathic lack of function. It occurs both sporadically and in families. In some cases, it develops as part of a polyglandular disorder and is thought to have an autoimmune basis. DiGeorge syndrome is a group of congenital disorders involving the branchial pouches that produces partial or complete agenesis of the thymus and parathyroid glands. Hypoparathyroidism can also develop in newborns as a result of prenatal suppression of the fetal parathyroid glands as a consequence of maternal hypercalcemia.¹⁷ It is also common in otherwise normal but premature infants.

Vitamin D Deficiency. Vitamin D deficiency can occur as a result of dietary deficiency or lack of sun exposure. Likewise, renal disease produces a decrease in the 1-hydroxylase activity

necessary for the formation of active vitamin D. The result is a decrease in calcium absorption and an increased secretion of PTH by the stimulated parathyroid glands. Osteomalacia, abnormal fractures, and the deformities of rickets may result.

Pseudohypoparathyroidism. Pseudohypoparathyroidism is a familial disease characterized by a rotund appearance, shortening of the extremities, and sometimes mental deficiency. The defect is not in PTH secretion; in fact, most patients have elevated plasma levels of PTH with evidence of increased bone resorption. Rather, the kidney is unresponsive to the hormone, and as a consequence, hypocalcemia and hyperphosphatemia develop. The deficit appears to be in the renal adenyl cyclase system.

Hypomagnesemia. This unusual deficit may result from chronic alcoholism, malabsorption, parenteral nutrition, or increased renal clearance during therapy with aminoglycosides. The deficit appears to block the physical response to PTH in addition to its release from the parathyroid gland.

Other Causes. In short-gut syndrome, after extensive small-bowel resection or bypass, or after some forms of bariatric surgery, vitamin D and calcium may be absorbed in insufficient quantities. In pancreatitis, the massive soft tissue destruction and saponification that occur with hemorrhagic disease may sequester significant amounts of calcium in the retroperitoneum. Some undefined systemic factor also appears to contribute to hypocalcemia in these patients. Hypoalbuminemia causes a reduction in the total plasma calcium level, although the level of ionized calcium remains within the normal range and patients are asymptomatic. Circulatory substances, such as the citrate used to anticoagulate banked blood and radiographic contrast media, may bind to calcium. In patients with osteoblastic metastases, particularly associated with prostate carcinoma, hypocalcemia has been attributed to increased calcium flux into the lesions. Toxic shock syndrome is sometimes associated with hypocalcemia, but the mechanism has not been defined. Acute hyperphosphatemia, as a consequence of exogenous administration of phosphate or during the cytolytic chemotherapy of highly responsive tumors (e.g., Burkitt lymphoma and acute lymphoblastic leukemia), may produce symptomatic hypocalcemia associated with soft tissue calcification.

Treatment

The treatment of hypocalcemia is summarized in Table 76.7. For acute symptomatic hypocalcemia, calcium should be administered intravenously. Calcium gluconate is less irritating to the veins than calcium chloride, and the calcium release is slower, without a risk for overcorrection. Usually, 20 to 30 mL of 10% solution is infused over a 15- to 20-minute period, and then 50 to 100 mL is administered over the next 12 hours in adults. A practical guide after an initial bolus dose includes 60 mL of 10% calcium gluconate in a 500-mL bag of dextrose 5% in water, infused at 1 mL/kg per hour, and adjusted every 4 hours based on the serum level of calcium and patient symptoms. Bicarbonate precipitates any calcium infused through the same intravenous line. Serum magnesium should always be measured, and hypomagnesemia should be corrected if present. In patients with convulsions from advanced tetany, diphenylhydantoin therapy is useful, but symptoms should never be allowed to progress to this point.

Long-term therapy is gauged on the basis of symptoms. In the postoperative patient, the continued stimulus of mild hypocalcemia to any remaining parathyroid gland tissue may prove useful. Concomitant therapy with calcium and vitamin D is effective in a timely fashion. A starting dose of 2 g of oral calcium carbonate per day in divided doses is usually well

TABLE 76.7

TREATMENT

TREATMENT OF HYPOCALCEMIA

■ SYMPTOM OR GOAL	■ TREATMENT
Symptomatic hypocalcemia	Oral calcium carbonate or intravenous calcium gluconate, and possibly vitamin D supplements to increase the efficiency of absorption of oral supplements
Symptomatic tetany	Intravenous calcium gluconate
Correction of hypomagnesemia	Intravenous magnesium chloride
Vitamin D supplementation	Ergocalciferol, calcifediol (liver disease), calcitriol (renal disease)
Long-term therapy	Calcium carbonate; low-phosphate, low-oxalate diet; parathyroid grafting (immunosuppressed or cryopreserved autograft)

tolerated. Vitamin D can be administered as calcitriol, an active synthetic vitamin D analogue. Most adults respond to a dose of 0.5 to 1.0 $\mu\text{g/d}$; reduced doses may be necessary for patients with renal dysfunction.

HYPERPARATHYROIDISM

Definitions

Parathyroid neoplasms are rarely identified by physical enlargement but rather are sought because of the peripheral effects of excess hormone. Primary hyperparathyroidism develops spontaneously, without apparent cause but possibly in response to exogenous stimuli. When the normal control of serum calcium is disturbed and the autonomous production of PTH is increased, the state is referred to as *primary hyperparathyroidism*. This category includes both benign single- and multiple-gland enlargements and the much rarer parathyroid carcinoma. In some cases, the disease is familial. In contrast, *secondary hyperparathyroidism* occurs when a defect in mineral homeostasis leads to a compensatory increase in parathyroid function. This occurs most commonly in response to renal disease but may also develop as a consequence of the hypocalcemia associated with some diseases of the gastrointestinal tract, bones, or other endocrine organs. Occasionally, with prolonged secondary stimulation, the hyperfunctioning glands are no longer physiologically responsive to an increase in ionized calcium. This uncommon (affecting about 2% of patients after renal transplantation), relatively autonomous state, referred to as *tertiary hyperparathyroidism*, develops most commonly after renal transplantation when the renal defect in calcium homeostasis is corrected.

Incidence

The advent in the 1970s of the widespread assessment of serum calcium as part of automated multichannel analysis has considerably altered our understanding of hyperparathyroidism. Before that time, primary hyperparathyroidism was thought to be a relatively rare condition. Most patients presented with symptoms of disease, usually renal stones or bony manifestations. Currently, most patients are asymptomatic or have only vague symptoms or signs that can be related to hyperparathyroidism.^{18,19} Occasionally, patients recognize that they had symptoms only after their well-being improves following parathyroidectomy. Incidence varies with both age and gender (Table 76.8), but hyperparathyroidism is believed to develop in about 50 to 100 people per 100,000 in the general population,

with approximately 50,000 new cases occurring annually in the United States.^{20,21} Marked variations have been noted worldwide; the reasons for these differences remain unclear.

Etiology

The cause of primary hyperparathyroidism is not known. Although the sequence of progression from secondary to tertiary disease in response to chronic stimulation has a logical appeal, it is difficult to draw parallels with primary disease. Most patients with primary hyperparathyroidism have disease of a single rather than of multiple glands, which is not what might be predicted if an external stimulus were part of the pathophysiology. Hyperparathyroidism is most common in postmenopausal women, the population group with the highest incidence of osteoporosis and the most significant alterations in calcium and phosphate metabolism. Loss of renal function with aging is associated with elevations in PTH and decreases in phosphate clearance. It has been suggested but not demonstrated that a renal calcium leak, if sufficient, might result in a chronic calcium deficit stimulating the parathyroid glands.

Genetic studies of parathyroid adenomas have described an oncogene (*PRAD1*) that may be one step in the path to neoplasia in these tumors. Overexpression of the normal *PRAD1* gene, also known as *cyclin D1*, allows progression of the cell cycle from the G1 phase to the S phase, thus promoting cellular growth and division. *PRAD1* is overexpressed in 20% to 40% of parathyroid adenomas; further research may reveal

other genetic alterations that contribute to the neoplastic growth. The *MEN1* tumor-suppressor gene has also been implicated in the molecular pathogenesis of sporadic hyperparathyroidism. About 15% to 20% of sporadic parathyroid adenomas have either somatic mutation or biallelic deletion of the *MEN1* gene.²²

Hyperparathyroidism occurs in several familial forms. It is a major component of the multiple endocrine neoplasia (MEN) syndromes types 1 and 2A. The parathyroid disease of MEN-1 syndrome is multiple parathyroid adenomas that appear with increasing frequency over the patient's lifetime.²³ In other families, hyperparathyroidism is inherited in an autosomal dominant fashion without other manifestations of MEN-1 or MEN-2; some have osseous abnormalities (tumor-jaw syndrome) and some apparently have isolated disease.

Pathology

Single-gland Versus Multiple-gland Disease. Microscopically, the cell most commonly involved in primary hyperparathyroidism is the chief cell. Less frequently, the oxyphil cell is the predominant cell type. Diseased glands typically have an increase in the proportion of stromal cells and a reduction in the proportion of stromal fat. Single diseased glands, or adenomas, have been classically described with a predominance of chief cells centering in a single focus, with a compressed rim of surrounding normal tissue (Fig. 76.8). In contrast, parathyroid hyperplasia has been characterized as a diffuse proliferation of clear cells in multiple glands, with little remaining normal tissue (Fig. 76.9). These criteria have proved totally unreliable. Although pathologic studies can usually distinguish parathyroid glands from other tissue, they may not prove useful beyond this capacity. Intraoperative decisions frequently depend on recognizing disease of one or more parathyroid glands, and in this regard, the histologic description of adenoma or hyperplasia is generally unreliable in primary hyperparathyroidism.²⁴

Patients with multiple-gland disease may have one gland that appears to be an adenoma and another that appears diffusely involved or even histologically normal with gross enlargement. The most reliable index of abnormality is the determination of glandular enlargement by visual inspection. The incidence of single- and multiple-gland enlargement as judged by visual inspection in 66 consecutive patients with hyperparathyroidism is shown in Table 76.9. The visual assessment and judgment of the experienced surgeon have proved to

FIGURE 76.8. Parathyroid adenoma. The tumor consists of sheets of neoplastic chief cells and is separated from normal parenchyma by a thin capsule. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

FIGURE 76.9. Primary parathyroid hyperplasia. The normal adipose tissue of the gland has been replaced by sheets and trabeculae of hyperplastic chief cells. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

be an effective basis for intraoperative decisions. This approach requires that all four parathyroid glands be evaluated at the time of operation. However, the recent ability to rapidly measure PTH during operation has provided a method to assess gland function rather than size. This experience indicates that there may be more enlarged glands than there are hyperfunctioning glands.²⁵

Carcinoma. Parathyroid carcinoma is a rare entity, and the histologic diagnosis can be exceedingly difficult. The surgeon may suspect the diagnosis when dense invasion and scarring are encountered, although this may also be secondary to some other inflammatory disease in the neck. Pathologic criteria include marked mitotic activity, dense fibrous stroma, and evidence of local invasion into the capsule or surrounding vessels.²⁶ Malignant-appearing tumors, however, may pursue an apparently benign clinical course; the converse is less frequently true. The only reliable criteria of malignancy are metastases, most commonly to the lymph nodes, lung, or liver, and true local invasion.

Systemic Effects

The use of automated technology for determining serum calcium has changed not only the estimated incidence of hyperparathyroidism but also the usual mode of presentation. Before screening, three fourths of patients presented with renal disease, particularly nephrolithiasis; one third to one half had

TABLE 76.9

GLAND ENLARGEMENT IN 66 CONSECUTIVE PATIENTS WITH PRIMARY HYPERPARATHYROIDISM

■ PATHOLOGY	■ PATIENT, <i>n</i>	■ PERCENTAGE
Adenoma	50	76%
Double adenoma	4	6%
Hyperplasia	12	18%

skeletal manifestations; and rare patients had both. Most recent series suggest that at least half of the patients in whom hyperparathyroidism is diagnosed do not have renal or osseous disease and many are minimally symptomatic or asymptomatic. Manifestations of the disease are protean but generally nonspecific, and they may be difficult to elicit in the history. A significant proportion of patients present without a readily quantifiable index of disease severity. This finding has created some controversy about the need for surgery in the asymptomatic patient and particularly for the elderly or high-risk patient.^{21,27}

The earliest complaints are often the vague symptoms of hypercalcemia. These vary with the magnitude of plasma calcium elevation and can include muscle weakness, anorexia, nausea, constipation, polyuria, and polydipsia. These nonspecific symptoms may or may not cause the patient to seek medical attention. Some symptomatic patients have evidence of chronic disease involving the kidney or skeleton. Usually, only one of these systems is significantly involved in any individual patient. The treatment of hyperparathyroidism is designed to eliminate or halt the progression of the complications of the disease. Symptomatic patients can be divided into two groups. Members of the first group have renal manifestations, a slower onset of symptoms, and generally lower serum calcium concentrations. Patients in the second group have a more rapid onset of symptoms, higher serum calcium levels, and significant bone disease. No recognizable histologic or physiologic characteristics distinguish patients with renal disease from those with bone disease.

Renal Manifestations. Renal complications develop because the hypercalcemia leads to an increase in urinary calcium excretion and because PTH increases the excretion of phosphate and produces urinary alkalosis. Both these events predispose to stone formation. Urinary stones can be treated surgically or with lithotripsy, and subsequent definitive treatment of the hyperparathyroidism reduces the rate of re-formation. Of patients who present for the first time with renal colic, 5% to 10% are found to have primary hyperparathyroidism. Nephrocalcinosis (Fig. 76.10) is calcification of the renal parenchyma and occurs in 5% to 10% of patients with hyperparathyroidism. It causes more significant renal damage than nephrolithiasis does. In

FIGURE 76.10. Abdominal film demonstrating nephrocalcinosis, or diffuse calcification of the renal parenchyma (arrows).

FIGURE 76.11. Magnification radiograph of the fingers in hyperparathyroidism. Subperiosteal cortical resorption (arrows) typically is most visible on the radial aspect of the middle phalanges.

general, the more severe the renal damage, the less likely it is that nephrocalcinosis will regress after parathyroidectomy.

The incidence of hypertension in hyperparathyroidism increases with the degree of renal impairment. Hypertension may be a significant cause of the morbidity associated with hyperparathyroidism, but although a decrease in blood pressure has been demonstrated in some patients after parathyroidectomy, the correlation between the two conditions is not clear.

Skeletal Manifestations. Parathyroid bone disease in its most classic and severe form, osteitis fibrosa cystica, is seldom encountered; however, 5% to 15% of patients with parathyroid bone disease present with significant symptoms of skeletal disease. Most commonly, these symptoms include bone pain and pathologic fractures.

Bone changes are often demonstrable on detailed plain radiographs of the hands (Fig. 76.11). Characteristically, subperiosteal resorption is evident on the radial aspect of the middle phalanx of the second or third finger. Because of tufting of the distal phalanges, clubbing may be evident on physical examination. Other findings that typically involve the skull and long bones include bone cysts, “brown” tumors (i.e., localized proliferations of osteoclasts), and diffuse demineralization or granularity. More subtle bone loss can be detected by iliac crest bone biopsy or dual-energy x-ray absorptiometry scan. The risk of bone fracture increases with increasing severity of bone loss.

Gastrointestinal Manifestations. Hypercalcemia is clearly associated with nonspecific gastrointestinal complaints, including nausea, vomiting, constipation, and anorexia, but attempts to demonstrate a definite relation between hyperparathyroidism and either peptic ulcer disease or pancreatitis remain unconvincing. Hypercalcemia stimulates gastric acid secretion experimentally and clinically, and has been associated with pancreatitis. Therefore, a theoretic rationale for the complex of

hyperparathyroidism and gastrointestinal symptoms does exist.

Neuromuscular Manifestations. Neurologic and muscular complaints are those of hypercalcemia in general. Fatigability and proximal muscle weakness are among the most debilitating manifestations. Atrophy of type II muscle fibers, consistent with a neuropathic and not a myopathic cause, has been demonstrated. Sensory complaints include dysesthesia, a reduced vibratory sense, and stocking-glove sensory deficits.

Psychological Manifestations. The emotional disturbances of hyperparathyroidism are often subtle and difficult to quantify. As with other forms of hypercalcemia, they range from depression or anxiety to psychosis and coma. Patients undergoing parathyroidectomy frequently experience a sense of well-being and relief from fatigue and dullness postoperatively, even if they may have had no noticeable complaints preoperatively.

Other Manifestations. A variety of signs and symptoms of soft tissue calcification have been described. Nonspecific arthralgia, particularly involving the proximal interphalangeal joints of the hands, is characteristic. The incidence of chondrocalcinosis is increased. Pruritus, vascular and cardiac calcification, and band keratopathy of the cornea have all been noted. Some reports have suggested an increased risk of malignancy and coronary artery disease, but the effects remain unsubstantiated, and it is not clear if the mortality risk is modifiable by correction of hyperparathyroidism.²⁸⁻³⁰

Physical Findings. Except in patients with the classic deformities of advanced bone disease, the physical examination is seldom helpful. Diseased parathyroid glands are infrequently palpable, except in patients with parathyroid carcinoma. A mass in the anterior neck in a patient with primary hyperparathyroidism is most commonly a thyroid nodule.

Laboratory Findings. Tests for calcium, PTH, phosphate, bicarbonate, and magnesium, in addition to other laboratory tests, are useful to establish the diagnosis of hyperparathyroidism.

Calcium. Hypercalcemia is the single most important diagnostic finding; however, particularly in early or mild cases, serial analysis may show fluctuations in and out of the normal range. Coexistent hypoalbuminemia and acidosis may produce an

apparently normal total serum level of calcium, even though the ionized fraction is actually elevated. Serum concentrations of ionized calcium may be helpful in the patient with intermittent or mild hypercalcemia.

Parathyroid Hormone. PTH measurement is an important method for establishing the diagnosis of hyperparathyroidism. Because of the heterogeneity of the various circulating forms of PTH, measurement of C-terminal or N-terminal fragments give conflicting and confusing results. Intact hormone assays and whole molecule assays are the most dependable. The demonstration of an elevated plasma PTH concentration alone does not establish the diagnosis of hyperparathyroidism. With a simultaneous elevated serum calcium level, this finding is virtually diagnostic (Fig. 76.12).

Phosphate. PTH increases renal phosphate excretion and, in about half of patients, produces hypophosphatemia. In the presence of renal disease, however, the serum phosphate levels may be normal or significantly elevated.

Bicarbonate. PTH also increases bicarbonate excretion, so that a hyperchloremic metabolic acidosis may develop. It has been suggested that the finding of an elevated serum chloride-to-phosphate ratio may be helpful in the differential diagnosis of hypercalcemia. A ratio greater than 30 is considered highly suggestive of hyperparathyroidism.

Magnesium. Hypomagnesemia develops in 5% to 10% of patients with hyperparathyroidism. After parathyroidectomy, if both hypocalcemia and hypomagnesemia are present, it may be difficult to correct the calcium until the serum magnesium has been corrected.

Other Diagnostic Tests. A variety of special diagnostic tests for hyperparathyroidism are available. None is more specific than the measurement of serum concentrations of calcium and PTH, although they may be useful in equivocal cases. For example, the 24-hour urinary calcium excretion is usually elevated, but may be normal, in patients with hyperparathyroidism, although the finding is not specific for this disease. This test is helpful in identifying patients with familial hypercalcemic hypocalciuria, in whom the rate of urinary calcium excretion is low. Measurements of tubular reabsorption of phosphate below 30% suggest primary hyperparathyroidism. Urinary cAMP is generated

FIGURE 76.13. ^{99m}Tc sestamibi scan of a patient with a parathyroid adenoma. The radionuclide is present in both thyroid and parathyroid tissue on the 10-minute film; however, by 2 hours, the radionuclide has washed out of the thyroid and remains only in the right-sided parathyroid gland. This scan shows a 794-mg right upper parathyroid adenoma (arrow).

specifically as a consequence of PTH activation of renal tubular adenylyl cyclase. Increased urinary concentrations are identified in most patients with primary hyperparathyroidism. These measurements are rarely necessary because of the reliability of the intact PTH measurement.

Localization with Imaging Techniques. In order to try to simplify the operative approach to hyperparathyroidism, an attempt is usually made to localize enlarged glands preoperatively. In the hands of an experienced surgeon, the cure rate for hyperparathyroidism at the initial operation without preoperative localization exceeds 95% with the conventional full neck exploration. However, technologic developments have led surgeons to pursue alternatives to the full neck exploration. These innovations are increasingly accurate preoperative localization with ^{99m}Tc sestamibi scintigraphy or high-resolution ultrasound, combined with intraoperative intact PTH measurement that allows termination of the operation without visualization of all four parathyroid glands. Surgeons have used these technologies in various combinations to limit the extent of the neck exploration. All of the current alternative strategies, however, depend on a preoperative parathyroid localization study to direct the exploration.

The study most frequently used for imaging previously unoperated patients is ^{99m}Tc sestamibi scintigraphy (Fig. 76.13). Sestamibi scanning can identify the site of abnormal tissue in 75% to 80% of patients but has limitations in patients with small adenomas or multiple-gland disease. Sestamibi was originally developed for cardiac imaging. The use of a single nuclide with a short half-life and a high-energy profile has advantages in lateral, oblique, and three-dimensional imaging that technetium-thallium scanning, which was formerly used, does not provide.

High-resolution ultrasound examination of the neck is also used for localization of abnormal parathyroid tissue, particularly when it is available for use by the clinician. The current machines scan at high frequencies (10 to 13 MHz) that allow demonstration of small abnormalities in the neck (Fig. 76.14). The examination is best done by a clinician in real time, as that allows the most complete assessment of the neck, rather than scans performed by a technician for later review of still pictures by the physician. The sensitivity of cervical ultrasound for abnormal parathyroid glands is about the same as for sestamibi scanning. Ultrasonography is an operator-dependent technique. It is rapid and relatively inexpensive and can direct fine-needle aspiration for cytologic confirmation and immunoassay for PTH.

In patients with persistent or recurrent hyperparathyroidism, preoperative imaging is important to guide the exploration. High-resolution real-time ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and sestamibi scanning all appear to have comparable sensitivities of 50% to 60%. The results of these examinations may be less successful at centers without significant experience in their use.

Computed tomography is more expensive but less operator dependent than ultrasonography. It clearly is superior in identifying deeper structures and for examining the retrosternal mediastinum. MRI is considerably more expensive than CT and has not been shown to be superior. Most surgeons prefer to have results of two or more imaging tests that confirm an abnormality before exploration in the reoperative setting.³¹

Treatment

Indications for Surgery. Generally, the only practical therapeutic option is surgery. Nephrolithiasis, bone disease, and

FIGURE 76.14. Ultrasound views of parathyroid adenomas. A: Sagittal image of the upper pole of the right lobe of the thyroid gland, demonstrating a hypoechoic parathyroid adenoma posterior to the thyroid parenchyma. B: Sagittal image of the lower pole of the left lobe of the thyroid gland with an adjacent hypoechoic parathyroid adenoma measuring 9 mm in greatest dimension.

neuromuscular symptoms all respond well to surgical intervention. In contrast, surgery in patients with renal failure, hypertension, and psychiatric symptoms is not so uniformly successful, although it benefits some patients and is usually indicated in all except those at highest risk. The question of how to manage the large group of patients with apparently asymptomatic disease requires particularly careful consideration.

Management of Asymptomatic Hyperparathyroidism.

- 4 A large proportion of patients with the diagnosis of hyperparathyroidism are minimally symptomatic or asymptomatic. The appropriate treatment for these patients remains controversial. Although little evidence indicates that irreversible complications, such as renal failure, eventually develop in patients with asymptomatic mild disease, the natural history of the disease remains incompletely defined. Many of the manifestations of this disease may go unrecognized until they are corrected surgically. Still unanswered is the question of how much asymptomatic disease may contribute to generalized osteopenia in this predominantly postmenopausal female population.

One study followed a group of 142 asymptomatic patients without operation.²³ At the end of the 10-year study, more than 20% of the patients had required surgery for an increase in serum calcium to above 11 mg/dL or for specific complications attributable to the disease. Another 20% were lost to or declined follow-up. The remaining patients either died of unrelated causes or had persistent asymptomatic disease. The authors concluded that because of the large percentage (about 40%) of patients who either required operation or were lost to follow-up, they could not reliably recommend conservative management.

A more recent report detailed the 15-year natural history of 116 patients with asymptomatic hyperparathyroidism.²¹ Operation was recommended for those in whom symptoms or findings developed, according to the guidelines of the National Institutes of Health Consensus Conference (see later). During the monitoring period, 51% of the patients had operation, and biochemical normalization and increased bone mass were observed in those who underwent surgery. However, the patients who did not undergo operative correction continued to have biochemical abnormalities and the cortical bone mass fell significantly. These data confirm the impression of most clinicians that mild hyperparathyroidism rarely takes a precipitously worsening clinical course; however, the differential bone effects that are evident by 15 years call into question how long such patients can be monitored without correction.

In October 1990, a National Institutes of Health Consensus Development Conference reviewed the available evidence regarding the management of asymptomatic primary hyperparathyroidism.³² After interval developments, a panel of experts reconvened in 2002 and revisited this issue.²⁰ The panel agreed that operation is the indicated treatment for all patients with symptoms; however, they recognized a subgroup of patients who have no symptoms attributable to hyperparathyroidism, and their conclusions included several indications for surgical intervention in these asymptomatic patients (Table 76.10).

The panel mandated close (every 6 months) follow-up for those patients not treated by operation. In addition, they recommended surgery for cases in which medical surveillance is neither desirable nor suitable, such as when a patient requests surgery, consistent follow-up is unlikely, coexistent illness complicates management, or a patient is younger than age 50 years.

This remains an area of considerable controversy. The complication rate of operation by an experienced surgeon is very low. Within a short period, the financial cost of medical follow-up exceeds that of treatment by operation. Based on these considerations, most patients should undergo operation, and those who do not must be closely followed.

TABLE 76.10 INDICATIONS/CONTRAINDICATIONS

NATIONAL INSTITUTES OF HEALTH CONSENSUS DEVELOPMENT CONFERENCE'S INDICATIONS FOR SURGICAL INTERVENTION IN PATIENTS WITH ASYMPTOMATIC PRIMARY HYPERPARATHYROIDISM

- Markedly elevated serum calcium (>1.0 mg/dL above normal)
- History of an episode of life-threatening hypercalcemia
- Reduced creatinine clearance
- Presence of one or more kidney stones detected by abdominal radiography
- Markedly elevated 24-h urinary calcium excretion
- Substantially reduced bone mass as determined by direct measurement (dual-energy x-ray absorptiometry T score < -2.5)

Principles of Surgical Correction

Although neck exploration for hyperparathyroidism may be straightforward, it sometimes becomes an arduous procedure requiring considerable patience because of the variability in both the location and the number of diseased glands. Persistent hyperparathyroidism and the necessity for reexploration can usually be avoided by a meticulous initial procedure. Reoperation is predictably more difficult than the initial operation, and the risks for damage to the recurrent laryngeal nerves and hypoparathyroidism are greater during reoperation.

It is essential that the surgeon be confident of the preoperative diagnosis and prospectively discuss the procedure with the patient. The potential complications of damage to either the recurrent laryngeal nerve or the superior laryngeal nerve and the development of hypocalcemia require discussion. Likewise, the possibility of an unsuccessful initial operation must be explained, and the patient should recognize that reexploration, including median sternotomy, may be required. Although alternatives to full neck exploration are often now applied, no patient should be explored by a surgeon who is unfamiliar with the principles and techniques of the conventional full neck exploration.

For a full neck exploration, the patient is placed under general anesthesia with a roll beneath the shoulders and the neck extended. The neck is opened through a transverse incision overlying the thyroid isthmus, and the platysma is similarly divided. Superior and inferior flaps are developed. The strap muscles are separated in the midline and retracted laterally; division is unnecessary. One lobe of the thyroid is chosen and rotated medially. Important landmarks include the tracheoesophageal groove, the recurrent laryngeal nerve, the inferior and superior thyroid arteries, and the middle thyroid vein (Fig. 76.15). In most patients, the nerve lies in the tracheoesophageal groove or just laterally. Occasionally, it may be situated more anteriorly. Uncommonly, it may originate directly from the vagus without passing around the right subclavian artery. Both of these latter variations make the recurrent nerve more susceptible to injury. The external branch of the superior laryngeal nerve, which innervates the cricothyroid muscle, usually lies medial to the superior thyroid vessels and should be carefully preserved.

For a full neck exploration, all four glands should be identified at the initial exploration because of the possibility of multiple-gland disease. Supernumerary glands may be present and should be sought at the initial procedure. Although frozen section has not been helpful in differentiating diseased from normal glands, it is generally reliable for confirming the presence or absence of parathyroid tissue. Small, thin biopsy specimens are sharply incised from the gland, with extreme care

FIGURE 76.15. Lateral view of the right side of the neck after rotation of the thyroid lobe. The important anatomic landmarks are emphasized.

taken to avoid damaging its delicate blood supply. Most surgeons use frozen section selectively to confirm suspected abnormal parathyroid tissue or to document difficult or confusing situations.³³

The upper glands are usually located far dorsally on the surface of the thyroid lobe at the level of the upper two thirds of the gland. The lower glands are less constant and may be located anywhere from well above the thyroid to the anterior mediastinum. The lower glands are most typically in the region where the thyrothymic ligament attaches to the lower pole of the thyroid lobe. If the inferior glands cannot be localized, the thymic pedicle should be carefully examined and mobilized. Because of their common embryologic origin, the inferior gland is frequently associated with the thymic remnant. Parathyroid glands within the mediastinum sometimes can be removed by mobilizing the thymus through the cervical incision. If this technique is unsuccessful in identifying the parathyroid gland, the thyroid lobe on the side of the missing gland is mobilized and palpated. Intraoperative ultrasonographic examination may identify an intrathyroidal parathyroid gland. As a last resort, excision of the thyroid lobe may be indicated.

If after meticulous exploration of all these areas three or four parathyroid glands have been identified, none of which is enlarged, most surgeons favor terminating the operation.

Limited Surgical Exploration

- 5 With the availability of accurate preoperative localization methods, it has become routinely possible to identify abnormal parathyroid glands prior to operation for most patients. This allows the surgeon to know where to start the exploration. Then, intraoperative PTH measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation. This strategy of directed, limited neck exploration is applicable to about 75% of initial parathyroid explorations, and has about the same success rate as full neck exploration.^{34–36} The preoperative localization can be done by either ^{99m}technetium sestamibi nuclear medicine scan or by high-resolution ultrasound. The intraoperative PTH measurement is first assessed at the outset of the procedure and/or immediately preceding parathyroid gland excision (the pre-excision baseline). Blood samples are obtained at time intervals after parathyroid gland resection. A decrease of the PTH level by 50% from the higher of the incision or pre-excision baseline predicts long-term normocalcemia.³⁷ Other investigators use

more sensitive criteria for the detection of multigland disease, including reduction of the PTH level into the normal range and kinetic assessments of the rate of PTH decrease.³⁸ This increase in sensitivity comes with the cost of decreased specificity, however. Blood samples can be obtained either centrally or peripherally.³⁹

The limited nature of this operative approach also makes it easier to perform this operation under regional or local anesthesia in an ambulatory setting. However, because of the possibility of multiple-gland disease or inaccurate preoperative localization, all surgeons undertaking this approach should also be skilled in the full neck exploration for hyperparathyroidism.^{40–42}

Extent of Resection. The operative procedure performed has been based on the number of enlarged glands identified at full neck exploration; however, with the use of intraoperative PTH monitoring, it has become clear that not all enlarged parathyroid glands are hyperfunctioning.⁴³ In contrast, nearly all hyperfunctioning glands are enlarged and hypercellular. The full neck exploration experience has demonstrated that removing all enlarged glands is a highly successful approach to curing hyperparathyroidism, and in the absence of PTH monitoring, this remains an accepted approach. Typically, single-gland disease has been treated by simple excision, whereas any combination of two- or three-gland enlargement is treated by resecting the diseased tissue and leaving the normal glands in place. The question of whether two- or three-gland enlargement implies the presence of disease in all glands (hyperplasia) has not been resolved. If one gland is large and the remaining three are normal in size, resection of the single parathyroid cures virtually all patients. Of 76 patients with two- or three-gland disease treated by excising the large glands and leaving the normal glands, only eight (10.5%) had recurrent hypercalcemia, which tended to be mild (follow-up of 12 to 140 months postoperatively). This approach seems satisfactory in most patients.⁴⁴

Treating patients with four-gland disease has been more difficult. In many of these patients, the disease occurs as a component of one of the familial syndromes, particularly MEN-1. Patients with four-gland parathyroid disease can be treated by subtotal parathyroidectomy (removing three and a half glands) or by total parathyroidectomy with autotransplantation of some parathyroid tissue into the nondominant forearm. Both operations depend on meticulous identification of all parathyroid tissue for adequate results. The putative advantage of the subtotal parathyroidectomy is that it leaves

the remaining parathyroid tissue with its native blood supply. Total parathyroidectomy with autograft has the advantage of removing all the abnormal parathyroid tissue from the neck and placing it in a site where reoperation for recurrent hyperparathyroidism is simpler.

The reported incidence of recurrent hypercalcemia after subtotal parathyroidectomy for nonfamilial parathyroid hyperplasia is 0% to 16%; the incidence of permanent hypoparathyroidism is 4% to 5%. Total parathyroidectomy with autograft is associated with a similar risk for permanent hypoparathyroidism in the sporadic setting (5%) and a higher reported risk for recurrent hypercalcemia (20%). Reoperation for recurrent hypercalcemia is greatly simplified by the approach of total parathyroidectomy with autotransplantation. Thus, given the current data, sporadic parathyroid hyperplasia can be acceptably treated by either operation. In patients with MEN-1, the disease is not the same as sporadic hyperplasia. Rather, defects in the *MEN1* gene cause multiple parathyroid adenomas that arise independently over the life of the patient.²³ The operative results reflect this independent capability of all parathyroid tissue in these patients to become neoplastic. The hypercalcemia recurrence rate is 26% to 36% with long-term follow-up after subtotal parathyroidectomy, and similar after total parathyroidectomy with autograft. However, the incidence of permanent hypoparathyroidism after autograft in MEN-1 is also significant (reported as high as 46%). While both approaches are currently accepted, most experienced centers now advocate subtotal parathyroidectomy as the initial operation in MEN-1 hyperparathyroidism, and anticipate that recurrent disease is likely, manageable, and less problematic than permanent hypocalcemia.⁴⁵⁻⁴⁸

Technique of Parathyroid Autotransplantation. The parathyroid gland is sliced into 15 to 20 pieces and autografted into a forearm muscle bed. The sites are marked with silk sutures. This location permits easy subsequent access under local anesthesia if recurrent hypercalcemia develops. Function of the autograft is documented by (a) normocalcemia, with the autograft as the only source of PTH; (b) by measuring higher concentrations of hormone in the antecubital vein draining the graft bed than in the corresponding vein in the opposite arm; or (c) “transient parathyroidectomy,” by placing a venous occlusive tourniquet on the arm above the graft and measuring changes over several minutes in the PTH levels drawn from the contralateral arm.⁴⁹ Lack of function is unusual outside of the MEN-1 patients; hypoparathyroidism develops in about 5% of patients. Glands can also be cryopreserved in dimethyl sulfoxide and serum. If in the postoperative period it becomes clear that the patient is a parathyroid, the cryopreserved tissue can be reimplanted under local anesthesia.

Special Situations

Persistent or Recurrent Hyperparathyroidism. Persistent hyperparathyroidism occurs in fewer than 5% of patients after exploration by an experienced surgeon. Most commonly, it is the result of a single diseased gland remaining in the neck or the mediastinum. Recurrent disease develops after an interval of normocalcemia and may be the result of regrowth of diseased tissue, implantation from a tumor broken at the initial procedure, or recurrent parathyroid carcinoma.

In the evaluation of these patients, it is essential to document that the initial diagnosis was correct. Familial hypocalcemic hypercalcemia should be excluded by measuring urinary calcium excretion.

Reviewing the original operative notes and pathology reports may provide clues to the position of missed glands. The locations of parathyroid tumors not found at the initial operation but identified on subsequent exploration in one large series are shown in Fig. 76.16.

FIGURE 76.16. Location of parathyroid tumors missed on initial exploration but identified on subsequent operation. (After Jaskowiak N, Norton JA, Alexander HR, et al. A prospective trial evaluating a standard approach to reoperation for missed parathyroid adenoma. *Ann Surg* 1996;224:308-320.)

It is generally agreed that localization studies do have a place in the management of recurrent disease. Noninvasive methods are used first, and if these are unsuccessful in identifying the diseased gland, selective angiography and venous sampling for PTH are used. The utility of the techniques vary across institutions, dependent on local experience, expertise, and preference. Selective angiography localizes 50% to 80% of parathyroid glands that cannot be detected by any other modality. Venous sampling may also be helpful in some patients, although interpretation can be complicated by the collateralization that occurs postoperatively. Because it provides no direct image but indicates the side and level of the neck where the hyperfunctioning tissue is located, it may help to direct the evaluation of imaging studies and the exploration to one or the other side of the neck. Both these invasive radiographic techniques require considerable expertise. Transient cortical blindness, transverse myelitis, and cerebrovascular accidents have all been reported as complications of arteriography. Angiographic ablation of mediastinal parathyroid tissue with large doses of ionic contrast has been successful in selected patients. This technique may be used in some patients with mediastinal parathyroid adenomas who are at increased surgical risk and who have other functional parathyroid tissue remaining.⁵⁰

Surgical reexploration can be a difficult procedure. The neck should almost always be reexplored first. If the thymic remnant has not already been removed, it should be excised at this time. Two adjunctive techniques, intraoperative ultrasonography to locate glands and intraoperative measurement of PTH to document the adequacy of resection, may be useful in patients undergoing operation for persistent disease.³¹

If the gland is not identified in the neck by means of the maneuvers described, the mediastinum is examined; most surgeons do this only if there is imaging evidence of disease in the mediastinum, rather than unguided exploration. Median sternotomy and exploration are necessary in only 1% to 2% of patients with hyperparathyroidism. Successful transcervical mediastinal exploration is sometimes possible with use of the Cooper thymectomy retractor, a substernal retractor that permits more extensive mediastinal exploration and thymectomy through a cervical incision.⁵¹ Any remaining thymic tissue is first isolated and examined. Inferior parathyroid glands most commonly migrate into the anterior mediastinum. If the results of this exploration are negative, the area posterior and lateral to the trachea is then explored. The location of superior

parathyroid glands may be as far posterior as the esophagus and as far superior as the pharynx.

Surgical reexploration is successful in experienced hands in about 80% of cases. The incidence of complications is increased. Unilateral recurrent nerve injury occurs in 5% to 10% of patients postoperatively, and permanent hypoparathyroidism in 10% to 20% of patients. Cryopreservation of excised tissue may be included as a component of the management of these patients because it allows later autotransplantation if the patient becomes hypoparathyroid postoperatively. However, the demonstration of continued PTH production by intraoperative PTH measurement makes cryopreservation unnecessary. The risks of these complications must be clearly outweighed by the clinical improvement in patients with advanced disease. Reoperation in asymptomatic patients with mild disease is controversial.

Hypercalcemic Crisis. Occasionally, patients with hyperparathyroidism become acutely hypercalcemic with severe symptoms. The pathogenesis appears to involve a cycle of uncontrolled PTH secretion followed by hypercalcemia and secondary polyuria, dehydration, and reduced renal function, which exacerbate the hypercalcemia. Serum calcium concentrations may reach 16 to 20 mg/dL, and the syndrome is manifested by rapidly developing muscle weakness, nausea and vomiting, lethargy, fatigue, and even coma. Ultrasonography, sestamibi scan, or CT scan may help to identify the enlarged gland to allow expedient correction.

Definitive treatment involves resecting the diseased parathyroid tissue, which is almost always curative. Generally, however, it is safer to lower the serum calcium level before operation.

Hyperparathyroidism in Pregnancy. Hyperparathyroidism in pregnancy is a rare disorder that not only causes hypercalcemia in the mother but also is associated with increased morbidity and mortality rates in the fetus. Even the newborn is at risk for the development of tetany. The risk for fetal complications is higher if the hyperparathyroidism is left untreated. The mother should undergo operation in the second trimester.^{17,52,53}

Neonatal Hyperparathyroidism. Neonatal hyperparathyroidism occurs in infants who are homozygous for a mutation of the calcium-sensing receptor and is characterized by hypotonia, poor feeding, constipation, and respiratory distress. Each parent of these children is affected by familial hypocalciuric hypercalcemia. The 1-year survival rate in children with symptoms is less than 50%, and patients without symptoms appear to have significant bone disease. Total parathyroidectomy with autotransplantation is the treatment of choice.⁵⁴

Secondary Hyperparathyroidism. Secondary hyperparathyroidism develops as a consequence of chronic renal failure. Phosphate retention and hyperphosphatemia reduce the serum calcium levels. This effect is aggravated by the reduction in 1-hydroxylase activity in the kidney, necessary for the activation of vitamin D₃. The secondary increase in PTH levels to compensate for the hypocalcemic effects is exacerbated by aluminum accumulation in bone. Aluminum, present both in the dialysate fluid and in phosphate-binding medications, contributes to the osteomalacia (renal osteodystrophy) that develops in all these patients after several years of dialysis. Therapy includes controlling the hyperphosphatemia with dietary restriction and phosphate-binding gels, calcium supplementation orally and in the dialysate bath, correction of acidosis, administration of vitamin D sterol, and reduction in aluminum intake in both the dialysate and the diet. Therapy should be initiated carefully because metastatic soft tissue calcification can occur. Indications for surgical therapy include persistent, symptomatic hypercalcemia that cannot be controlled medically, particularly in prospective renal transplant patients; bone pain and abnormal fractures; ectopic calcification; and intractable pruritus. Subtotal parathyroidectomy and total parathyroidectomy with heterotopic autotransplantation both appear to be acceptable options, although reexploration for

recurrent disease is less complicated after total parathyroidectomy with autotransplantation. Parathyroidectomy can enhance aluminum deposition, so any excess should be corrected preoperatively through chelation.

Parathyroid Carcinoma. Parathyroid carcinoma is a rare condition, accounting for less than 1% of all cases of hyperparathyroidism. Histologic criteria remain controversial, and the diagnosis is securely made only on the basis of local invasion or distant metastases. In comparison to patients with benign disease, these patients tend to be somewhat younger and more symptomatic. In contrast to the marked female predominance in benign disease, the male-to-female ratio in carcinoma is equal. Serum calcium, PTH, and alkaline phosphatase levels are relatively more elevated, and patients often have an elevated level of human chorionic gonadotropin. Patients may have manifestations of both renal and bone disease. The affected gland is palpable in almost half of patients.

Initial treatment should include radical resection of the involved gland, ipsilateral thyroid lobe, and regional lymph nodes. Neither chemotherapy nor radiation therapy has shown any benefit. If the disease recurs, resection should be attempted because without treatment these patients usually succumb to uncontrolled hypercalcemia. The long-term prognosis is poor, and the opportunity for survival depends on complete initial resection.^{26,55,56}

MULTIPLE ENDOCRINE NEOPLASIA

Although these familial disorders are typically characterized by a predisposition to the development of tumors of multiple endocrine organs, the parathyroid is characteristically involved in two of them. The disorders are all inherited in an autosomal dominant fashion, and the tumors tend to be multicentric. The tumors can be benign or malignant and can occur metachronously or synchronously. MEN-1 is characterized by the concurrence of parathyroid hyperplasia, pancreatic islet cell tumors, and pituitary adenomas. MEN-2A consists of medullary thyroid carcinoma (MTC), pheochromocytoma, and parathyroid hyperplasia. MEN-2B includes MTC, pheochromocytoma, mucosal neuromas, and a distinctive marfanoid habitus. Together these syndromes encompass much of the spectrum of endocrine neoplasia.

Pathogenesis

The genetic abnormality in MEN-1 has been identified and described in detail.^{57,58} As a tumor-suppressor gene, the first mutation is inherited and becomes unmasked only when a second mutation, in some cases a deletion, develops in susceptible tissues. The resulting complete loss of the tumor suppressor allows neoplasia to develop. The occurrence of multiple second mutations explains the characteristic multicentric involvement of these diseases. Direct genetic testing is now available for some families with known mutations.

Mutations of the *RET* proto-oncogene are the cause of MEN-2A.^{59,60} Genetic testing is now available to identify affected family members and provide the opportunity for early treatment of MTC in affected persons.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 1

Characteristically, MEN-1 presents in the third and fourth decades, without any gender predilection.⁶¹ The syndrome is expressed with nearly complete penetrance, and autopsy studies suggest that all three organs are affected in more than 90% of patients. The phenotype varies, however; more than 90% of patients have hyperparathyroidism, but evidence of islet cell

neoplasms (30% to 80%) and pituitary tumors (15% to 50%) is less common. The cause of death in carriers of the MEN-1 mutation is related to MEN-1 in about 45% of patients and often caused by malignant islet cell or carcinoid tumors.⁶²

Parathyroid Disease. Hypercalcemia secondary to hyperparathyroidism is usually the first biochemical abnormality detected in MEN-1 and represents the best screening opportunity for members of affected kindreds until direct genetic screening is available in a specific family. Many of these patients are asymptomatic and have relatively mild hypercalcemia. When symptoms do develop, they typically involve the urinary tract rather than the skeleton.

Typically, the patients have four-gland disease, which may be particularly difficult to manage. The disease is characterized by metachronous development of multiple parathyroid adenomas. There is no curative operation; the two accepted approaches (subtotal parathyroidectomy and total parathyroidectomy with autograft) each have faults (see earlier). Over time, the subtotal parathyroidectomy approach is becoming the preferred choice by most surgeons.

Pancreatic Tumors. In patients with pancreatic tumors, multicentric and diffuse hyperplasia of the pancreatic islets may occur in areas distant from any grossly evident tumor. The management of these tumors is controversial because although some patients have aggressive, malignant tumors, many patients have a fairly benign course. No reliable criteria are available to detect malignant tumors. Tumor size is often cited as a useful marker of prognosis, but substantial overlap has been noted between the sizes of primary benign and malignant tumors (Fig. 76.17).⁶³ Because of the difficulty in identifying the more aggressive subset, some authors have chosen a liberal policy of early operation to try to prevent metastasis and death. Pancreatic tumors are typically multicentric and frequently malignant. Somatostatin receptor scintigraphy can be a useful imaging technique to demonstrate the extent of tumor (Fig. 76.18).⁶⁴

Gastrinoma is the most common functional tumor in MEN-1; typically, a severe ulcer diathesis (Zollinger-Ellison syndrome) develops that is associated with secretory diarrhea. Serum gastrin levels are usually markedly elevated ($>1,000$ pg/mL); when levels are equivocal (250 to 1,000 pg/mL), provocative testing with secretin (2 m/kg) may be useful. An absolute serum gastrin increase of 200 pg/mL is diagnostic. The primary tumors are often in the submucosa of the duodenal wall.

Biochemical cure of these gastrinomas is almost never possible, which is different than patients with sporadic gastrinomas, although exploration can reduce the need for antise-

FIGURE 76.17. Scatter plot of largest primary tumor size versus metastatic status in 43 patients with pancreatic islet cell tumors associated with multiple endocrine neoplasia type 1. Each point represents a single patient. Tumor size is not correlated with the presence of liver or lymph node metastases. (Reproduced with permission from Lowney JK, Frisella MM, Lairmore TC, et al. Islet cell tumor metastasis in multiple endocrine neoplasia type I: correlation with primary tumor size. *Surgery* 1998;124:1043–1049.)

FIGURE 76.18. Somatostatin receptor scintigraphy in a patient with multiple endocrine neoplasia type 1. This scintiscan detected an otherwise unrecognized metastasis to the left lateral segment of the liver (white arrow), which was resected along with the small primary tumor (black arrow).

tory medications and may reduce the risk for liver metastasis. Histamine 2–receptor antagonists or proton pump inhibitors are effective in controlling acid secretion, although very high doses may be necessary; the malignant disease is often indolent. Total gastrectomy is no longer ever necessary to eliminate acid secretion.

Insulinoma is the next most common functional pancreatic neoplasm in MEN-1. Patients present with a history of sweating, dizziness, confusion, and syncope, consistent with neuroglycopenia; these symptoms are relieved by consuming carbohydrates. The diagnosis is verified by documenting fasting hypoglycemia associated with inappropriately elevated plasma insulin levels. Preoperative tumor localization is usually achieved by a combination of CT and arteriography. Calcium is injected into various pancreatic arteries and plasma insulin levels in the hepatic vein plasma are measured to detect a gradient after the injection of specific pancreatic arteries localizing the area of the pancreas containing the functional tumor.

Because the available medical therapy for insulinoma is limited, patients are treated operatively. Lesions in the tail of the gland can be enucleated if they are small; however, distal pancreatectomy carries little morbidity. Tumors of the head can usually be enucleated, so that pancreaticoduodenectomy can be avoided. In patients with malignant disease, metastases may respond to streptozocin; diazoxide, verapamil, or octreotide, may successfully reduce insulin secretion and control symptoms. A diet of complex carbohydrates can also help stabilize serum glucose levels in the hyperinsulinemic patient.

Nonfunctional tumors are the most common pancreas lesions in MEN-1. Their management is specific to their size and risk of malignancy.

Pituitary Adenomas. Prolactin-secreting tumors occur most commonly in this setting, although Cushing disease or acromegaly develops in an occasional patient. Symptoms may result from compression of the optic chiasm, which produces bitemporal hemianopsia, or from prolactin excess, which produces amenorrhea and galactorrhea in female patients and hypogonadism in male patients.

Bromocriptine inhibits prolactin secretion and shrinks many prolactinomas. Refractory tumors and those producing other hormones can be managed by pituitary ablation or radiation.

Other Tumors. MEN-1 is associated much less frequently with adrenocortical tumors and benign thyroid adenomas. Lipomas and carcinoid tumors may also occur.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 2

Like MEN-1, the MEN-2 syndromes are inherited in an autosomal dominant fashion with complete penetrance but variable phenotype. Bilateral MTC occurs in every affected patient. More frequently than the other syndromes, MEN-2B can arise as a new mutation that can be transmitted to subsequent generations.

Medullary Thyroid Carcinoma. Medullary thyroid carcinoma accounts for about 10% of all thyroid malignancies, and 20% of cases occur in the familial setting of MEN-2A, MEN-2B, or familial non-MEN MTC. It is usually the first tumor that develops in these patients and typically appears in the second or third decade. Tumors are virtually always bilateral and develop in multiple areas of the middle and upper portions of the thyroid lobe (Fig. 76.19). Occasionally, in young people, a diffuse proliferation of parafollicular C cells, termed *C-cell hyperplasia*, is present without frankly invasive carcinoma. This finding is highly suggestive of one of the familial MTC syndromes. Patients typically present with a neck mass and may have hoarseness, dysphagia, or palpable cervical adenopathy. MTC may produce a variety of hormones, including calcitonin, adrenocorticotrophic hormone, prostaglandin, and serotonin. The hypercalcitoninemia is often asymptomatic, although severe diarrhea can develop.

By detecting minimal elevations of plasma calcitonin, it is possible to diagnose MTC at a clinically occult stage. Basal plasma calcitonin levels in normal subjects are in the range of 30 to 100 pg/mL. An increase to levels of 150 to 200 pg/mL occurs, however, after the administration of the potent secretagogues calcium and pentagastrin. The plasma calcitonin levels of patients with MTC show striking increases ($>1,000$ pg/mL) after provocative testing, so that they can be identified readily. Patients with occult disease may have only minimally elevated basal calcitonin levels that increase in response to secretagogues. The combined infusion of calcium and pentagastrin was the most effective screening test for familial MTC before genetic testing became available. By means of provocative testing in kindred members at risk for disease, MTC was diag-

nosed at a preclinical stage, and a greater percentage of these patients were cured by surgical therapy. With genetic testing now available, prophylactic thyroidectomy to prevent the development of MTC is possible for all affected people.

Postoperatively, the presence of residual MTC can be readily detected by provocative testing. Meticulous reoperation in patients with recurrent or persistently elevated plasma calcitonin levels postoperatively, including mediastinal dissection on occasion, can normalize elevated plasma calcitonin levels and apparently cure many of them.⁶⁵ For the patient with unresectable metastases, few therapeutic options are available. Neither radiation nor chemotherapy is of significant benefit.

The clinical course of patients with the MEN-2 syndromes is determined primarily by the status of their MTC. In the setting of MEN-2A, the tumors are often indolent and survival prolonged, even in the presence of metastatic disease. By contrast, the tumors in patients with MEN-2B occur at an earlier age and are generally more aggressive neoplasms. Patients may succumb to the disease at a young age. As a consequence of this aggressiveness, the size of kindreds with the disease is typically small, and usually only a few generations are affected.

Pheochromocytoma. Pheochromocytomas are usually detected during the initial screening or follow-up of patients in whom MTC has already been diagnosed. They typically appear in the second or third decade of life, and about 80% are bilateral. Usually, pheochromocytomas are benign but multicentric, and they almost always arise in the adrenal medulla. In patients with MEN-2A or MEN-2B, hyperplasia of the adrenal medulla may develop first, grossly characterized by thickening of the medullary tissue in both adrenal glands.

Pheochromocytomas can be asymptomatic, but most commonly, patients have pounding frontal headaches, episodic diaphoresis, palpitations, or anxiety. Hypertension also occurs and is often episodic.

The diagnosis is made by measuring the plasma concentration of metanephrines. Patients with MEN-2A or MEN-2B and MTC should be evaluated for pheochromocytoma before they undergo thyroidectomy. If a patient is found to have both lesions, adrenalectomy should be performed first, followed by neck exploration. The abdomen is explored through a bilateral subcostal incision or, more typically, with a laparoscope.⁶⁶ Bilateral pheochromocytomas are treated by bilateral adrenalectomy. In patients with MEN-2A or MEN-2B and a unilateral pheochromocytoma, only the diseased adrenal gland is removed. In about 30% of patients treated in this manner, a tumor eventually develops in the opposite gland. In the remaining patients, this approach avoids the need for glucocorticoid and mineralocorticoid replacement and the risk for Addisonian crisis. After unilateral adrenalectomy, patients are carefully screened at 6-month or 1-year intervals with plasma metanephrine measurements.

Parathyroid Disease. Hyperparathyroidism develops in about one third of patients with MEN-2A, although it is usually asymptomatic. Occasionally, nephrolithiasis develops. Bone disease is unusual. Frequently, enlarged parathyroid glands are found at operation for MTC, although the patient is still normocalcemic. Multiglandular chief cell hyperplasia is the predominant histologic finding in MEN-2A. Significant parathyroid disease rarely develops in MEN-2B.

Total parathyroidectomy and heterotopic autotransplantation are performed in hypercalcemic patients with MEN-2A. In normocalcemic patients with MEN-2A undergoing thyroidectomy for MTC, total parathyroidectomy and heterotopic autotransplantation are performed in one session to ensure that the complete thyroidectomy does not compromise the parathyroid blood supply and to avoid reoperation in the neck for subsequent hyperparathyroidism. Evidence suggests that these patients are more easily treated, with a lower incidence of recurrent hyperparathyroidism, than patients with MEN-1.

Nonendocrine Manifestations of Multiple Endocrine Neoplasia Type 2B

In addition to MTC and pheochromocytoma, marked abnormalities of the nervous and musculoskeletal systems develop in patients with MEN-2B. The classic phenotype is characterized by thick lips and a thin, marfanoid habitus (Fig. 76.20A, B). The incidence of associated skeletal abnormalities is high;

these include kyphosis, pectus excavatum, pes planus or cavus, and congenital dislocation of the hip. Diffuse autonomic nervous hypertrophy is another feature. Mucosal neuromas appear on the tongue (Fig. 76.20C), eyelids, lips, and pharynx. Slit-lamp examination may reveal hypertrophied corneal nerves. Ganglioneuromatosis develops in the submucosal and myenteric plexuses of the gastrointestinal tract. Constipation is common, and radiographic findings may suggest megacolon or Hirschsprung disease.

CHAPTER 77 ■ ADRENAL GLAND

JOHN A. OLSON, Jr., AND RANDALL P. SCHERL

KEY POINTS

- 1 Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives of cholesterol that are either extracted from plasma or synthesized intracellularly.
- 2 Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine, the vasoactive synthetic derivatives of the amino acid tyrosine.
- 3 Cushing syndrome is adrenocorticotrophic hormone dependent in 80% to 90% of cases, most often because of an ACTH-secreting pituitary adenoma, though ectopic ACTH-producing nonendocrine tumors (mostly non-small cell lung cancer and bronchial carcinoids) represent 10% to 20% of cases of ACTH-dependent Cushing syndrome; the remainder have a primary adrenal cause of hypercortisolism.
- 4 An aldosterone-producing adrenal adenoma (Conn syndrome) is the source of primary hyperaldosteronism in 60% to 70% of cases whereas idiopathic bilateral adrenal hyperplasia causes most of the remaining cases of primary hyperaldosteronism; adrenocortical carcinoma is a rare cause of primary hyperaldosteronism.
- 5 Surgical removal by laparoscopic adrenalectomy of an aldosterone-secreting adenoma results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients; management of idiopathic adrenal hyperplasia is medical, because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy.
- 6 The congenital adrenal hyperplasias are autosomal recessive conditions resulting from inherited defects of one or several of the enzymes necessary for cortisol biosynthesis leading to ACTH overproduction and secondary hyperplasia of the adrenal cortex with shunting of cortisol precursors into adrenal androgen pathways; peripheral conversion of the excess adrenal androgens to testosterone causes virilization of the patient.
- 7 Adrenocortical carcinoma has an estimated incidence of 0.5 to 2 cases per million per year and is very aggressive (most patients present with locoregionally advanced or distant disease); hormone overproduction syndromes are frequent including hypercortisolism, hyperaldosteronism, or virilization.
- 8 The *rule of tens* is a useful way to characterize pheochromocytoma: Tumors are bilateral in 10% of cases, extra-adrenal in 10%, familial in 10%, multicentric in 10%, and malignant in 10%, and occur in children in 10% of cases; determination of plasma-fractionated metanephrines is the best test for diagnosis of pheochromocytoma.
- 9 Unsuspected adrenal masses are detected by computed tomography in 0.6% to 1.9% of healthy patients; the goal of evaluation is to distinguish and remove those adrenal masses that are functioning or likely to be malignant versus those that are neither and can be observed.

ANATOMY

The adrenal glands are bilateral, retroperitoneal, endocrine organs located adjacent to the superior pole of each kidney. These glands appear grossly as flat, triangular structures each weighing approximately 4 g. Each adrenal gland is composed of two distinct endocrine organs, the cortex and medulla. The outer adrenal cortex is bright yellow and nodular, whereas the adrenal medulla is red-brown and is sandwiched between the thin layers of the cortex. The adrenals are embedded in retroperitoneal perinephric fat but can be identified as distinct structures by their golden brown, nodular appearance. The right adrenal gland abuts the inferior vena cava medially and lies in close proximity to the diaphragmatic crus posteriorly and the liver anteriorly. The left adrenal gland resides between the kidney and aorta, immediately deep to the tail of the pancreas and spleen.

Embryologically, fetal and definitive adrenal cortices arise from coelomic mesoderm near the urogenital ridge during the fourth to sixth weeks of gestation. Postnatally, the fetal cortex involutes, leaving only the definitive cortex to differentiate into the three adult zonae, the glomerulosa, fasciculata, and reticularis. The adrenal medulla develops from the neural crest during the fifth gestational week and migrates along paraaortic and paravertebral routes to join the developing cortex. Ectopic adrenal cortex and medulla may be found anywhere along their respective paths of embryologic migration. Most

neural crest tissue regresses; however, extraadrenal neural crest derivatives may be found along the retroperitoneum and at the aortic bifurcation (organ of Zuckerkandl).

The adrenal cortex is composed of three distinct zones. The outer zona glomerulosa, located just beneath the fibrous gland capsule, is the site of mineralocorticoid production. The middle zona fasciculata, composed of linear arrays of large, foamy cells with lipid inclusions, is the predominant site of glucocorticoid and adrenal sex steroid biosynthesis. The inner zona reticularis is the primary location of synthesis of adrenal androgens. Both the zona fasciculata and zona reticularis respond to stimulation by adrenocorticotrophic hormone (ACTH). The adrenal medulla is smaller than the cortex. Cells of the adrenal medulla appear as homogeneous sheets, with large, irregular, atypical-looking nuclei. The cytoplasm of these cells has numerous secretory granules containing catecholamines, neuron-specific enolase, and chromogranin. Catecholamines in these granules precipitate chromium salts, which is the basis for the term *chromaffin cells*.

The adrenal glands have an extensive vascular supply derived from branches of the inferior phrenic artery superiorly, the aorta medially, and the renal artery inferiorly. Venous return from the right adrenal gland empties directly into the inferior vena cava through a wide but short central vein. Venous drainage from the left adrenal gland empties into a smaller vein that shares a common trunk with the left phrenic vein. Together they join the left renal vein (Fig. 77.1).

FIGURE 77.1. A: Arterial (dark shaded) and venous (light shaded) anatomy of the adrenal glands. B: Schematic showing outer adrenal cortex (light shaded) and inner adrenal medulla (dark shaded).

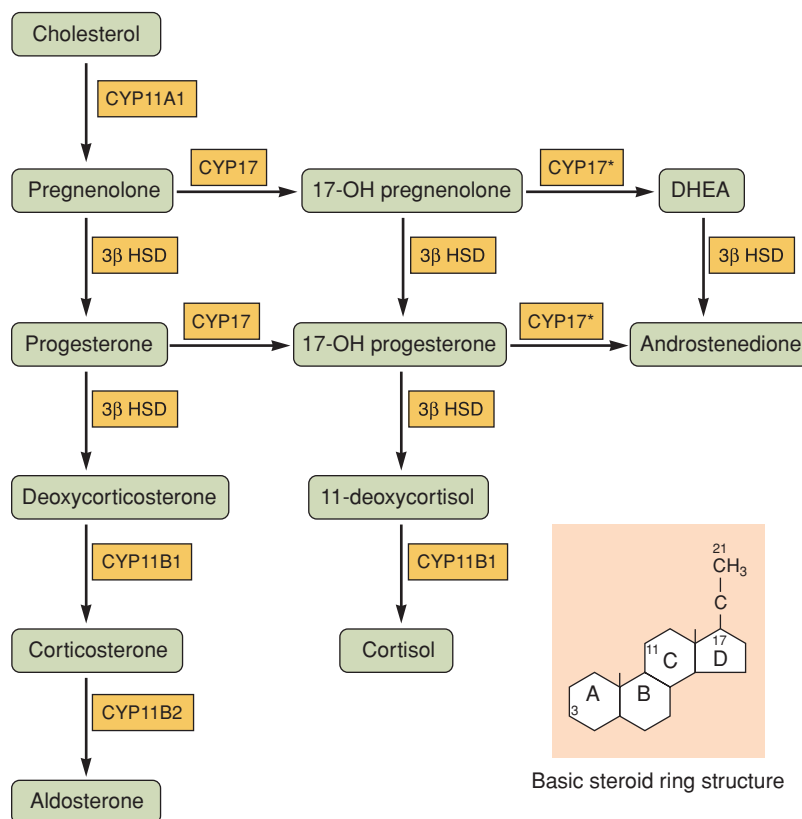

BIOCHEMISTRY AND PHYSIOLOGY

Adrenal Cortex

- Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives

of cholesterol that are either extracted from plasma or synthesized intracellularly (Fig. 77.2). In mitochondria of cells in the adrenal cortex, cholesterol is converted by desmolase (CYP11A1) to delta-5-pregnenolone, the common parent compound for all adrenal cortex steroids. Pregnenolone is then shunted to the three biosynthetic pathways, each compartmentalized within the adrenal according to synthetic capabilities within each zone. In the zonae fasciculata and reticularis,

FIGURE 77.2. Steroid biosynthetic pathways in the adrenal cortex. Steroids and precursors are shown in square boxes. Enzymes are shown in stippled boxes. Enzyme gene symbol designations are as follows: CYP11A1, desmolase; CYP17, 17 α hydroxylase >>>(±17,20 lyase*); 3 β HSD, 3 β hydroxysteroid dehydrogenase; CYP21A2, 21 hydroxylase; CYP11B1, 11 β hydroxylase; CYP11B2, aldosterone synthase. Inset: Basic steroid ring structure. The four basic carbon rings are designated A, B, C, and D. Individual carbons at sites of steroidogenic enzyme activity are designated numerically.

pregnenolone is either converted to progesterone by 3-beta-hydroxysteroid dehydrogenase or is oxidized at position 17 by 17-alpha hydroxylase (CYP17) to form 17-hydroxypregnenolone. In the zona fasciculata, progesterone is hydroxylated by CYP17 at position 17 to form 17-hydroxyprogesterone. Subsequently, 17-hydroxyprogesterone is sequentially hydroxylated at the 21 position by 21-beta hydroxylase (CYP21A2) and at position 11 by 11-beta hydroxylase (CYP11B1) to form cortisol. In the zona reticularis, the androgenic steroids dehydroepiandrosterone (DHEA) and androstenedione are made from 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively. Collectively, the glucocorticoid and androgenic steroids are known as *17-hydroxy corticosteroids* and *17-hydroxy ketosteroids*. In the zona glomerulosa, progesterone is not hydroxylated at the 17 position owing to the lack of enzyme at this location. Instead aldosterone is made from progesterone by a sequential series of hydroxylation steps at position 21 by CYP21A2, position 11 by CYP11B1, and position 18 by aldosterone synthase (CYP11B2 and P450c11as). The zona glomerulosa is well suited to aldosterone biosynthesis because of the relative lack of 17-hydroxylase and the exclusive expression of aldosterone synthase, required for the conversion of corticosterone to aldosterone.

Cortisol. Cortisol is the predominant glucocorticoid in humans. Production and release of cortisol is tightly regulated by a complex feedback relationship between the hypothalamus, corticotrophs of the anterior pituitary, and cells of the adrenal cortex zonae fasciculata and reticularis. This endocrine system is called the *hypothalamic-pituitary-adrenal (HPA) axis*. Communication within the HPA axis is mediated by synthesis and secretion of corticotrophin-releasing hormone (CRH) by the hypothalamus and ACTH production by corticotrophs of the anterior pituitary (Fig. 77.3). ACTH is a cleavage product of a precursor polypeptide, proopiomelanocortin (POMC) that is built of 241 amino acid residues within corticotroph cells of the anterior and intermediate lobes of the pituitary. Several

derivatives of POMC are important biologically active substances, including ACTH. Under stimulation of hypothalamic CRH, POMC can be cleaved into ACTH and β -lipotropic hormone in the anterior lobe. ACTH acts directly on the adrenal to regulate cortisol production by cells within the zonae fasciculata and reticularis. Feedback loops involving cortisol, hypothalamic CRH, and pituitary ACTH keep the concentration of cortisol in plasma within a narrow range of 10 to 15 $\mu\text{g/dL}$. Typical daily production of cortisol in humans ranges between 10 to 30 mg and can increase to as high as 300 mg per day under conditions of maximal stress.

In circulation, cortisol is protein bound to transcortin and albumin with a small percentage of free cortisol available to target tissues. The half-life of cortisol in circulation is 90 minutes. Cortisol is metabolized in the liver to the inactive metabolites dihydrocortisol and tetrahydrocortisol, which become conjugated to glucuronidase and excreted in the urine. These urinary metabolites, collectively known as *17-hydroxycorticosteroids*, as well as free cortisol, can be measured in the urine.

Cortisol binds to specific intracellular cytoplasmic receptors, causing translocation of activated receptor-ligand complexes to the nucleus. Biologic effects result from transcriptional activation of genes and may be grouped into intermediary metabolism, immunomodulation, and regulation of intravascular volume (Table 77.1). Important effects of cortisol on intermediary metabolism center on raising blood glucose directly and indirectly by providing substrate for gluconeogenesis by the liver. These effects include (a) stimulation of glucagon and inhibition of insulin-stimulated glucose uptake by cells; (b) decrease in peripheral protein synthesis and increase in proteolysis, thus delivering gluconeogenic amino acids to the liver; and (c) stimulation of peripheral lipolysis. In effect, cortisol acts anabolically in vital organs to preserve glucose supply and catabolically in peripheral tissues to mobilize gluconeogenic substrates. Cortisol also possesses profound anti-inflammatory and immunosuppressive activities. Impairment of cellular immunity is due to

FIGURE 77.3. Schematic of hypothalamic-pituitary-adrenal axis for cortisol. Regulatory feedback relationships are designated with arrows.

TABLE 77.1

SYSTEMIC EFFECTS OF CORTISOL

FUNCTION	NORMAL AMOUNTS	EXCESSIVE AMOUNTS
Metabolic		
Protein	Proteolysis	Muscle wasting
Glucose	Gluconeogenesis	Hyperglycemia
Fat	Low-use peripheral lipolysis	Limb thinness
	Central lipogenesis	Truncal obesity
Gastrointestinal	Mucosal cells	Ulceration

Cardiovascular	Chronotropic, inotropic	Hypertension
	Vascular resistance	
Renal	Sodium resorption	Hypertension
Bone	Osteoblastic development	Osteoporosis
Inflammatory and immune	Circulating cells	Infection
	Soluble mediators	
	Antigen processing	
Wound healing	Fibroblasts	Striae
	Epithelial cell	Dehiscence

FIGURE 77.4. Regulatory relationships of renin, the angiotensins, and their sites of production and enzymatic conversion.

inhibition of interleukin production, impairment of monocyte and neutrophil chemotaxis despite raised leukocyte counts, and reduction of T-cell activation. Humoral immunity is inhibited by inhibition of T-cell stimulation of B cells and by direct inhibition of B-cell proliferation and activation. These immunomodulatory effects may also underlie the impairment of normal wound healing seen in states of cortisol excess. Cortisol also regulates intravascular volume through renal retention of sodium and maintains blood pressure through inotropic and chronotropic effects on the heart as well as by increasing peripheral vascular resistance. In bone, glucocorticoids promote osteopenia by inhibition of bone formation by osteoblasts.

Aldosterone. Aldosterone is the principle mineralocorticoid in humans. Aldosterone secretion by the cells of the adrenal zona glomerulosa is regulated by the renin-angiotensin system and by plasma potassium (Fig. 77.4). Aldosterone is also regulated to a lesser degree by ACTH and plasma sodium concentration. Juxtaglomerular myoepithelial cells lining afferent arterioles of the kidney sense renal blood flow and pressure, and they secrete renin in response to decreased perfusion. Renin enzymatically activates angiotensinogen to the inactive decapeptide precursor, angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in the lung. Angiotensin II has three major effects: (a) arteriolar vasoconstriction; (b) renal sodium retention; and (c) increased aldosterone biosynthesis, each of which results in sodium retention and potassium excretion by the kidney. These effects work together to maintain arterial blood pressure as well as blood volume. Physiologic conditions that stimulate the renin-angiotensin cascade and aldosterone release include dehydration, upright posture, and hemorrhage. Inhibitory factors include volume repletion. Postural

changes in renin-angiotensin and aldosterone are mediated by the sympathetic nervous system.

Under normal circumstances, aldosterone secretion is controlled by total body sodium and potassium levels. Excess sodium intake suppresses renin activity and leads to decreased aldosterone levels and increased renal excretion of sodium. Conversely, sodium depletion stimulates the renin-angiotensin system and aldosterone production, which promotes sodium retention by the kidney. Increased potassium intake directly decreases renin release and aldosterone production; decreasing potassium intake increases renin release. Humans with normal sodium intake typically produce 100 to 150 mg of aldosterone per day.

In circulation, aldosterone is bound to albumin and transcortin with a small percentage of free aldosterone available to target tissues. The half-life of aldosterone in plasma is 15 minutes. Aldosterone is metabolized rapidly in the liver and conjugated to glucuronidase, which is excreted in the urine. In liver failure, metabolism of aldosterone is impaired leading to elevated levels and fluid retention.

Aldosterone is the major regulator of extracellular fluid volume and potassium homeostasis (Table 77.2). Aldosterone binds to high-affinity aldosterone receptors in target tissues, including cells of the distal convoluted tubule in the kidney (the major site of action), the salivary glands, and colonic mucosa (minor sites). Stimulation of these cells results in retention of sodium and excretion of potassium. Retention of sodium in the kidney leads to passive reabsorption of water and an increase in extracellular fluid volume. To balance aldosterone-mediated retention of positively charged sodium ions, the kidney epithelium releases intracellular potassium into the distal convoluted tubule for excretion in the urine.

TABLE 77.2**EFFECTS OF ALDOSTERONE SECRETION**

■ TUBULAR ACTION	■ NORMAL AMOUNTS	■ EXCESSIVE AMOUNTS
Increased resorption of sodium	Protects against low-volume states	Hypertension Positive sodium balance Hyporeninemia
Decreased resorption of potassium	Protects against hyperkalemia	Hypokalemia Metabolic alkalosis Hyperglycemia Nocturia, polyuria Muscle weakness

Hydrogen ion is also released causing acidification of the urine.

Adrenal Androgens. Adrenal C-19 androgenic steroids, which include DHEA and delta-4 androstenedione, are synthesized in cells of the zona reticularis. These steroids promote secondary sexual characteristics in men and virilization in women. DHEA is the major adrenal androgen, while androstenedione is relatively minor. Both are relatively weak androgens and exert their effects on target tissue after local tissue conversion to testosterone. Unlike gonadal androgens, adrenal androgens are regulated by ACTH, not gonadotropins, and can therefore be inhibited by glucocorticoid administration.

Adrenal Medulla

- 2** Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine. These vasoactive hormones are synthetic derivatives of the amino acid tyrosine (Fig. 77.5). The biosynthetic pathway that converts tyrosine to active catecholamines involves four sequential enzymatic reactions: (a) Tyrosine is converted to L-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase; (b) dopa is converted to dopamine by aromatic-L-amino acid decarboxylase; (c) dopamine is converted to norepinephrine by dopamine β hydroxylase; and (d) norepinephrine is converted to epinephrine by phenylethanolamine-N-methyltransferase (PNMT). Epinephrine is the major (80%) catecholamine stored in the adrenal medulla, followed by norepinephrine (20%) and dopamine (<1%). Tissue expression of the enzyme PNMT is limited to cells of either the adrenal medulla or organ of Zuckerkandl, located near the aortic bifurcation; thus most extraadrenal pheochromocytomas produce norepinephrine, rather than epinephrine.

A complex regulatory network governs synthesis and secretion of catecholamines. Factors that increase catecholamine release include splanchnic nerve stimulation, stress, and glucocorticoids. The metabolic milieu within the adrenal medulla also greatly influences catecholamine synthesis by regulating enzymatic activity: Glucocorticoids, phospholipids, cyclic adenosine monophosphate, adenosine triphosphate, protein kinase, and magnesium increase activity of PNMT and decrease catecholamine negative feedback. Catecholamines are stored and secreted from granules within cells of the medulla in association with the matrix protein chromogranin. Chromogranin A is measurable in the blood, and its measurement may support the biochemical testing for pheochromocytoma, as well as other functional neuroendocrine tumors.

Catecholamines act on target tissues through membrane-bound receptors. Pharmacologic distinction of adrenergic

receptors is made based on their relative responsiveness to natural and artificial bioamines. Alpha-adrenergic receptors show the highest affinity for norepinephrine, less for epinephrine, and least for isoproterenol. Beta-adrenergic receptors are most responsive to isoproterenol and least to norepinephrine. In addition, specific antagonists recognize each receptor class: Alpha-receptors are antagonized by phentolamine and phenoxybenzamine, and beta-receptors are blocked by propranolol and related compounds. Beta-adrenergic receptor subtypes include beta-1, which is present in cardiac muscle, adipose tissue, and small intestine, and beta-2 receptors, which are found in vascular, tracheal, and uterine smooth muscle, skeletal

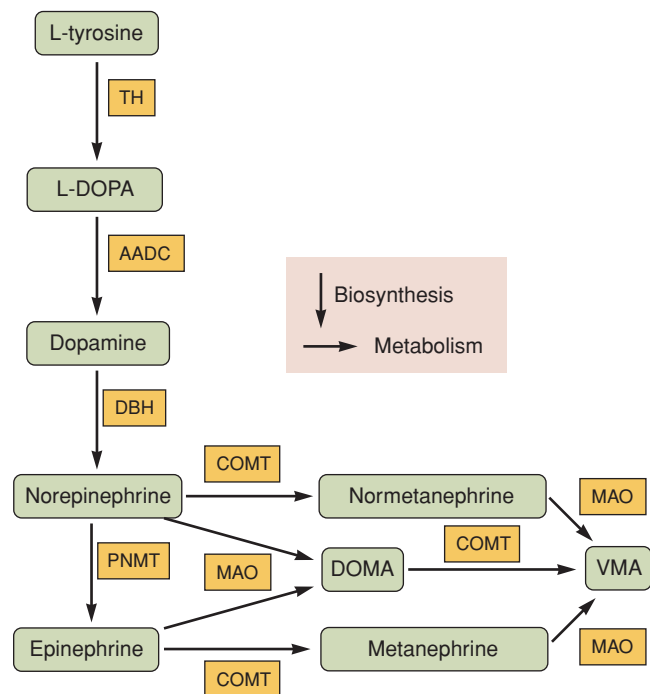

FIGURE 77.5. Catecholamine biosynthetic and metabolism pathways. Precursors, catecholamines, and metabolites are shown in square boxes. Enzymes are shown in stippled boxes. Enzyme gene symbol designations are as follows: TH, tyrosine hydroxylase; AADC, aromatic-L-amino acid decarboxylase; DBH, dopamine β hydroxylase; PNMT, phenylethanolamine-N-methyltransferase; COMT, catechol-O-methyl-transferase; MAO, monoamine oxidase; VMA, 3-methoxy-4-hydroxy-mandelic acid.

^aPlatelet aggregation.

muscle, and liver. Alpha-adrenergic receptors are similarly subdivided: Alpha-1 receptors mediate vasoconstriction whereas alpha-2 receptors modulate presynaptic norepinephrine release and platelet aggregation (Table 77.3).

Metabolism of catecholamines occurs through three mechanisms: by specific uptake by sympathetic neurons, by nonspecific uptake and degradation by peripheral tissues, and by excretion in the urine. Catecholamines are metabolized in liver and kidney by two enzymes, monoamine oxidase and catechol-O-methyltransferase (Fig. 77.5). In these tissues, monoamine oxidase and catechol-O-methyltransferase convert epinephrine or norepinephrine to normetanephrine, metanephrine, 3,4-dihydroxy-mandelic acid, and 3-methoxy-4-hydroxy-mandelic acid. These inactive metabolites are excreted by the kidney and are measurable in the urine either as free compounds or as conjugates of glucuronide or sulfate.

DISEASES OF THE ADRENAL CORTEX

Hypercortisolism

The term *hypercortisolism* refers to the physiologic state of glucocorticoid excess. This disorder is rare, with an estimated incidence of 10 per million population. The most common cause of hypercortisolism is the administration of exogenous steroids as immunosuppressive therapy for inflammatory disorders or after organ transplantation. Endogenous hypercortisolism, or Cushing syndrome, in all cases is caused by increased adrenal production of cortisol, which may be ACTH dependent (ACTH elevated) or independent (ACTH suppressed). Some patients with major depression or chronic alcoholism have abnormally high cortisol secretion and may appear to have clinical and biochemical features of Cushing syndrome. Pseudo-Cushing syndrome responds to treatment of the underlying disorder.

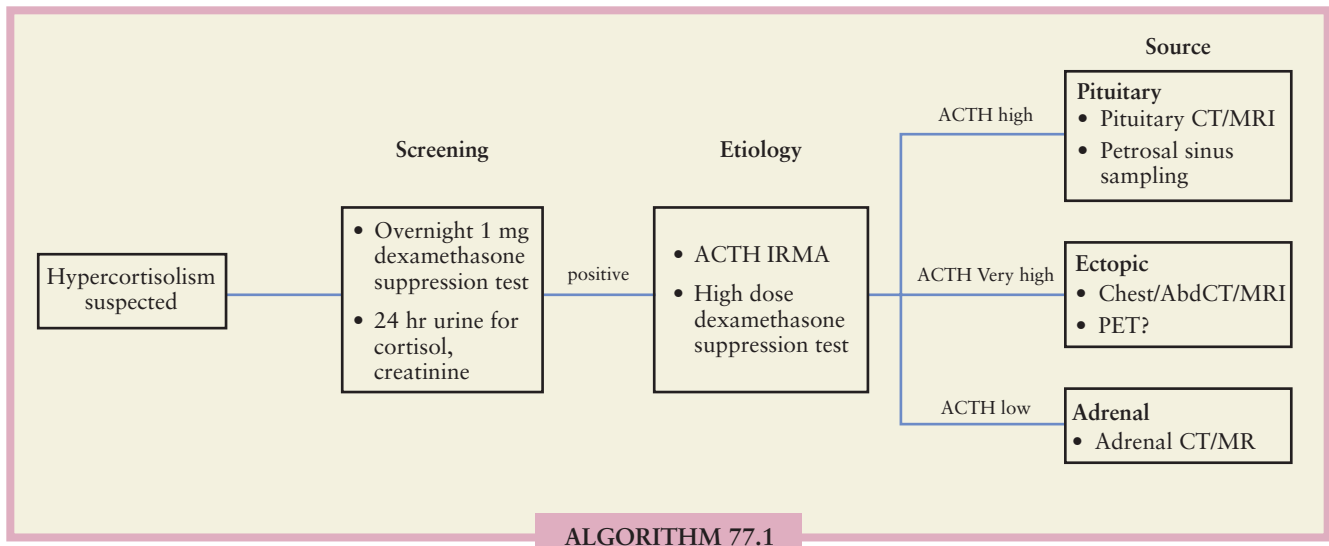

3 Cushing syndrome is ACTH dependent in 80% to 90% of cases. Such ACTH-dependent hypercortisolism is most often (80%–90% of cases) caused by an ACTH-secreting pituitary adenoma (termed *Cushing disease*). Ectopic ACTH-producing nonendocrine tumors (mostly non-small cell lung cancer and bronchial carcinoids) represent 10% to 20% of cases of ACTH-dependent Cushing syndrome. All causes of ACTH-dependent Cushing syndrome involve bilateral adrenal hyperplasia in response to ACTH stimulation.

4 Of patients with endogenous Cushing syndrome, 10% to 25% have ACTH-independent disease caused by a primary adrenal cause. A solitary adrenal adenoma is present in 80% to 90% of these patients and is often associated with atrophy of both adjacent and contralateral adrenocortical tissue. Nodular cortical hyperplasia of both glands causes the remaining cases of primary adrenal Cushing syndrome. Although nodular hyperplasia represents a diffuse process, one or more distinct nodules may simulate adenomas. Rarely tumors secrete CRH ectopically, leading to ACTH-independent (though ACTH is elevated) Cushing syndrome with secondary adrenal hyperplasia.

Signs and Symptoms. Clinical features of cortisol excess are listed in Table 77.1. Truncal obesity (*orange on toothpicks*), accumulation of fat around the head and neck (*moon facies* and *buffalo hump*), and muscle wasting are present in most patients. Patients often have purple striae and purpura on the abdomen and extremities. Hirsutism may be present in women. High blood pressure is common and is usually moderate, although malignant hypertension has been observed. Muscle weakness and bone pain, particularly backache, are also common. Weakness is caused partly by proximal muscle wasting but also by hypokalemia. Osteoporosis is common, and pathologic fractures are observed in advanced cases. Neurologic symptoms, including headache, emotional lability, depression, and even psychosis may be observed. Glucose intolerance is common but can often be managed by alterations in diet alone. The serum potassium level may be low secondary to the weak mineralocorticoid properties of cortisol. Autonomous glucocorticoid production without specific signs and symptoms of Cushing syndrome is termed *subclinical Cushing syndrome*. This condition is being diagnosed with increased frequency because of the detection of adrenal incidentalomas by routine CT. A substantial percentage of incidentalomas are hormonally active, with 5% to 20% of the tumors producing glucocorticoids. The estimated prevalence of subclinical hypercortisolism is 77 cases per 100,000 persons, substantially higher than classic Cushing syndrome. Depending on the amounts of glucocorticoids secreted by the tumor, the clinical spectrum ranges from slightly attenuated diurnal cortisol rhythm to atrophy of the contralateral adrenal gland. Patients with subclinical Cushing syndrome lack the classical stigmata of hypercortisolism but have a high prevalence of obesity, hypertension, and type 2 diabetes.

Diagnosis. The investigation of suspected Cushing syndrome should answer two questions: (a) Does the patient have hypercortisolism? (b) If the answer is yes, then what is the cause? It is worthwhile to emphasize that the diagnosis of Cushing syndrome is biochemical. Radiologic investigations should not be undertaken until Cushing syndrome has been confirmed and its likely etiology characterized biochemically.

Hypercortisolism insensitive to suppression by administration of exogenous glucocorticoid is the sine qua non of Cushing syndrome. The low-dose dexamethasone suppression test is the best test in patients with suspected Cushing syndrome. For this test, 1 mg of dexamethasone is administered orally at 11 p.m. and plasma cortisol is obtained at 8 a.m. the following day. Normal individuals suppress cortisol to less than 5 $\mu\text{g/dL}$. Patients with Cushing syndrome fail to suppress less than 5 $\mu\text{g/dL}$. False-positive test results occur in 10% to 15% of cases with the overnight test and occur especially in patients with obesity or alcoholism or in those taking estrogens or phenytoin. Measurement of free cortisol (not metabolites) in three consecutive 24-hour collections of urine is also a good screening test for Cushing syndrome. Collections should include concurrent creatinine measurement to evaluate the completeness of the collection. A 24-hour urinary free cortisol level greater than 100 μg is diagnostic of Cushing syndrome. This test may be less sensitive than the low-dose dexamethasone suppression test in mild hypercortisolism. Plasma cortisol levels can normally vary considerably

ALGORITHM 77.1. Diagnosis of hypercortisolism. ACTH, adrenocorticotropic hormone; IRMA, immunoradiometric assay; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

during a 24-hour period, so a single random plasma cortisol level is not helpful in establishing a diagnosis of Cushing syndrome.

Once the presence of hypercortisolism is established, the next task is to determine ACTH-dependent (pituitary or ectopic source) from ACTH-independent (primary adrenal) causes. Measurement of basal ACTH by immunoradiometric assay is the best test to make this distinction. Plasma ACTH levels are normally between 10 and 100 pg. Suppression of the absolute level of ACTH less than 5 pg per mL is nearly diagnostic of adrenocortical neoplasms, which secrete high levels of cortisol and inhibit ACTH release by the pituitary. Patients with pituitary neoplasms and secondary bilateral adrenocortical hyperplasia have ACTH levels that may range from the upper limits of normal (15 pg per mL) to 500 pg per mL. The highest plasma levels of ACTH (>1,000 pg per mL) are in patients with ACTH-producing nonendocrine tumors such as non-small cell lung cancer.

Although 80% to 90% of patients with ACTH-dependent Cushing syndrome have Cushing disease, a high-dose dexamethasone suppression test may be required to exclude ectopic ACTH syndrome. Hypercortisolism caused by ACTH-secreting pituitary adenomas is suppressed at least partially by high dexamethasone, whereas hypercortisolism caused by adrenal tumors and ectopic ACTH-producing tumors is not suppressed. For this test 2 mg dexamethasone is administered orally every 6 hours for 2 days, and a 24-hour urine collection for free cortisol is taken during the second day. About 90% of patients with pituitary source Cushing disease have a 50% reduction in urine free cortisol. The specificity of the test can be improved to 100% for diagnosing pituitary disease if more than 90% suppression in urinary free cortisol is used.

Biochemical testing of suspected Cushing syndrome is followed by radiologic studies. Pituitary adenomas are best imaged with gadolinium-enhanced MRI of the sella turcica, which has a sensitivity approaching 100%, although small pituitary microadenomas may be missed. Patients with ACTH-independent Cushing syndrome require thin-section CT or MRI of the adrenal, which identifies adrenal abnormalities with more than 95% sensitivity. CT or MRI of the chest may identify a source of ectopic ACTH and should be undertaken in patients with elevated ACTH and hypercortisolism that cannot be suppressed by high-dose dexamethasone.

Despite the accuracy of biochemical testing and radiographic localization, a pituitary versus ectopic source of

ACTH sometimes cannot be determined. Bilateral inferior petrosal sinus sampling is the best test to settle this issue. Simultaneous bilateral petrosal sinus and peripheral blood samples are obtained before and after peripheral intravenous injection of 1 μ g per kg CRH. An inferior petrosal sinus to peripheral plasma ACTH ratio of 2.0 at basal stimulated or of 3.0 after CRH administration is 100% sensitive and specific for pituitary adenoma. Comparison of right and left inferior petrosal sinus ratios may also lateralize the adenoma.

The laboratory approach to the diagnosis of Cushing syndrome is summarized in Algorithm 77.1. A careful history and physical examination form the basis for suspecting this condition. A low-dose dexamethasone suppression test and/or urinary free cortisol measurement provide initial evidence for the diagnosis. Plasma ACTH determination and the high-dose dexamethasone suppression test are then used to identify the underlying cause of excess cortisol production by the adrenal cortex. Imaging studies support the cause of Cushing syndrome suggested by biochemical testing and localize the site for subsequent treatment.

Treatment. ACTH-dependent Cushing syndrome is best treated by removing the source of ACTH excess. In the case of Cushing disease, transsphenoidal resection of the pituitary microadenoma is successful in 80% or more of cases. If a microadenoma is not found, then hemihypophysectomy may be performed with the understanding that fertility may be impaired. Pituitary irradiation is a good treatment option when fertility is desired, when a tumor is not found or is unresectable, or cure is not achieved by transsphenoidal resection of a tumor. Debulking of unresectable primary lesions or recurrences with or without bilateral adrenalectomy may provide palliation in some patients. Treatment of ectopic ACTH syndrome involves removal of the primary lesion. Medical adrenalectomy with metyrapone, aminoglutethimide, and mitotane has been used to suppress production of corticosteroid in inoperable cases for both pituitary and ectopic sources of ACTH. Bilateral adrenalectomy is a good option for patients intolerant of mitotane.

ACTH-independent Cushing syndrome is best treated by removal of the adrenal tumor and affected gland. Small lesions, less than 6 cm in diameter, may be resected laparoscopically. Lesions larger than 6 cm or those suspected of being carcinoma require an anterior open approach. Resection

of cortisol-producing benign adrenal adenomas is curative, and prognosis is good following resection. Cortisol-producing adrenocortical carcinomas recur frequently following adrenalectomy, heralded by the reemergence of hypercortisolism. Micronodular pigmented hyperplasia and macronodular adrenal hyperplasia may involve both adrenal glands. These conditions are cured only by bilateral adrenalectomy. Medical adrenalectomy with mitotane or agents interfering with cortisol production is not currently recommended.

Whether patients with subclinical Cushing syndrome should undergo adrenalectomy is unclear. Several small series have demonstrated weight loss and an improvement in hypertension and glucose control following adrenalectomy for subclinical Cushing syndrome. Furthermore, patients with subclinical Cushing syndrome may progress to overt Cushing syndrome as frequently as 12.5% at one year. Accordingly, adrenalectomy for subclinical Cushing syndrome may be beneficial and is reasonable in young patients, patients with suppressed plasma ACTH, and patients with a recent weight gain, substantial obesity, arterial hypertension, diabetes mellitus, and osteopenia. Truly asymptomatic patients with normal plasma ACTH concentrations and the elderly or unfit may be observed. Demonstration of the benefits of surgery versus conservative treatment in patients with subclinical Cushing syndrome will require a randomized prospective trial.

All patients who undergo adrenalectomy for Cushing syndrome require perioperative and postoperative glucocorticoid replacement, since the contralateral gland is suppressed. Replacement therapy with hydrocortisone, 12 mg/m² per day, may be required as long as 2 years postoperatively. Adequacy of replacement is monitored clinically. The duration of replacement therapy is guided by normalization of the ACTH stimulation test.

Hyperaldosteronism

Hyperaldosteronism is a syndrome of hypertension and hypokalemia caused by autonomous adrenal secretion of the mineralocorticoid aldosterone. Hyperaldosteronism may be primary, as a result of an adrenal neoplasm with suppressed plasma renin, or may be secondary, as a result of elevated plasma renin. Primary hyperaldosteronism is twice as common in women as in men, and it usually occurs between the ages of 30 and 50 years. Screening of hypertensive patients with plasma aldosterone and plasma renin activity (PRA) has suggested that primary hyperaldosteronism may be the underlying cause of up to 15% of cases of essential hypertension.

5 An aldosterone-producing adrenal adenoma (Conn syndrome) is the source of primary hyperaldosteronism in 60% to 70% of cases. Idiopathic bilateral adrenal hyperplasia causes the remaining cases of primary hyperaldosteronism. Adrenocortical carcinoma is a rare cause of primary hyperaldosteronism. Autosomal dominant glucocorticoid-suppressible hyperaldosteronism is a rare cause of hyperaldosteronism resulting from the fusion of the ACTH-responsive 11-beta hydroxylase gene promoter to the aldosterone synthase gene in cells of the adrenal cortex.

Secondary hyperaldosteronism is a physiologic response of the renin-angiotensin system to decreased renal perfusion due to renal artery stenosis, cirrhosis, congestive heart failure, and normal pregnancy. The adrenal cortex functions normally and secretes aldosterone in response to the elevated plasma renin and angiotensin caused by these conditions. Secondary hyperaldosteronism responds to treatment of the underlying cause.

Signs and Symptoms. Clinical manifestations of primary hyperaldosteronism are attributable to hypersecretion of aldosterone by the adrenal gland (Table 77.2). Aldosterone-mediated retention of sodium and excretion of potassium and hydrogen ion by the kidney causes moderate diastolic hyper-

tension. Edema is absent. Hypokalemia occurs spontaneously in 80% to 90% of patients with primary hyperaldosteronism but may be normal. Hypokalemia is easily provokable in the remaining patients. Potassium depletion frequently causes symptoms of muscle weakness and fatigue, polyuria and polydipsia, as well as impaired insulin secretion and fasting hyperglycemia. Primary hyperaldosteronism should be suspected in hypertensive patients with spontaneous hypokalemia (serum concentration <3.5 mEq/L), moderate hypokalemia (serum potassium concentration <3.0) during diuretic therapy despite concomitant use of oral potassium or potassium-sparing diuretics, or refractory hypertension without explanation.

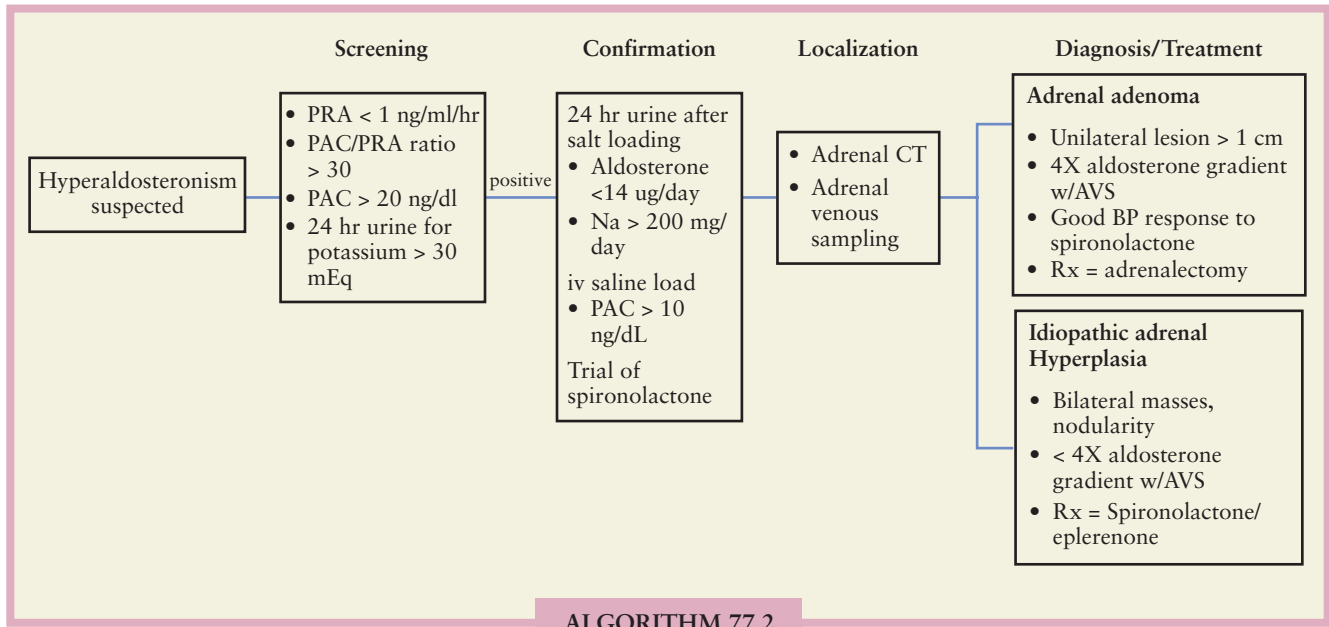

Diagnosis. The clinical hallmarks of primary hyperaldosteronism are (a) diastolic hypertension without edema; (b) suppression of plasma renin in the face of volume depletion; and (c) hypersecretion of aldosterone that fails to suppress with intravascular volume expansion. Diagnostic evaluation must establish primary hyperaldosteronism, discern surgically correctable adrenal adenoma from medically treatable idiopathic hyperplasia, and localize an adrenal tumor (Algorithm 77.2).

Demonstration of an elevated plasma aldosterone concentration (PAC) in the setting of suppressed PRA is the best test to establish primary hyperaldosteronism. The ratio in normal subjects and patients with essential hypertension is 4 to 10 compared with more than 30 in most patients with primary hyperaldosteronism. A PAC of greater than 20 ng/dL and a PAC/PRA ratio of greater than 30 are diagnostic for aldosteronoma with almost 90% sensitivity. A serum potassium value less than 3.5 mEq/L and urinary potassium excretion greater than 30 mEq per day also support a diagnosis of primary hyperaldosteronism. Before biochemical evaluation, patients need to be potassium repleted and have an adequate sodium intake. Medications including ACE inhibitors and spironolactone should be withheld for at least 4 weeks before study.

An elevated PAC/PRA ratio alone does not establish the diagnosis of primary hyperaldosteronism, which must be confirmed by demonstrating inappropriate aldosterone secretion with salt loading. This involves a 24-hour urine collection for sodium and aldosterone after 3 days of a high-sodium diet. The 24-hour urinary excretion of aldosterone should be greater than 14 µg per 24 hours after a high-salt diet for patients with primary hyperaldosteronism. An intravenous saline infusion test or captopril challenge test is also a reliable method to confirm primary hyperaldosteronism. These tests are not usually required.

After the diagnosis of primary hyperaldosteronism is made, distinction must be made between an aldosteronoma and idiopathic adrenal hyperplasia. The first test measures aldosterone in blood collected at 8 a.m. from a patient who has been supine overnight. Laboratory studies are repeated 4 hours later after the patient has been upright. Aldosterone secretion in patients with an aldosteronoma is unaffected by postural changes (<20 ng/dL), whereas, in patients with idiopathic adrenal hyperplasia, plasma aldosterone levels are elevated 33% (>20 ng/dL) or more by postural changes.

High-resolution adrenal computed tomography (CT) is the best test for localization of an adrenal tumor (Fig. 77.6). CT will detect an aldosterone-producing adenoma in 90% of cases overall. The presence of a unilateral adenoma greater than 1 cm on CT and supportive biochemical evidence of an aldosteronoma are generally all that is needed to make the diagnosis in most patients younger than 40 years of age. Magnetic resonance imaging (MRI) is less effective and more costly but may be useful during pregnancy or in situations in which intravenous contrast medium injection is undesirable. Scintigraphy with [6-beta](131I)-iodo-methyl-19-norcholesterol (NP-59) identifies functional tumors and discriminates aldosteronoma from adrenal hyperplasia with an overall accuracy of approximately 75%, but requires a tumor of sufficient size (>1 cm) for imaging to be dependable.

ALGORITHM 77.2

ALGORITHM 77.2. Diagnosis and management of hyperaldosteronism. PRA, plasma renin activity; PAC, plasma aldosterone concentration; CT, computed tomography; AVS, bilateral adrenal venous sampling.

Adrenal vein sampling to lateralize the source of aldosterone production is useful in patients with hyperaldosteronism when there is no adrenal abnormality on CT or MRI or when both adrenal glands are abnormal but asymmetric. Furthermore, patients older than 40 years, in whom the possibility of a nonfunctioning adenoma is statistically higher, may benefit from routine sampling. Percutaneous transfemoral cannulation of both adrenal veins is performed and intravenous ACTH (50 μ /h) is administered. Simultaneous adrenal vein blood samples for aldosterone and cortisol are taken before and after ACTH injection, and their ratios are determined. The PAC is markedly higher (at least fourfold) on the side of an adenoma, whereas there is little or no left-right gradient present in cases of bilateral adrenal hyperplasia. A 10-fold gradient of cortisol in adrenal veins to a peripheral sample

ensures adequate adrenal vein cannulation. This study is greater than 90% accurate and has been shown to alter management in 30% to 50% of patients, even in those with an apparent unilateral adenoma. This test is technically difficult and may be unsuccessful in 25% of patients. Emerging data suggest that adrenal vein sampling may be superior to CT in differentiating the source of aldosterone production in patients with hyperaldosteronism.

FIGURE 77.6. Computed tomography scan of right adrenal aldosteronoma. Short arrow shows aldosteronoma. Long arrow shows normal contralateral adrenal gland.

6 Treatment. Surgical removal of an aldosterone-secreting adenoma (Fig. 77.7) results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients. Laparoscopic adrenalectomy is the preferred approach to remove these tumors. Morbidity and mortality following these procedures are almost negligible. Preoperative spironolactone or eplerenone and potassium are given to replenish potassium stores and correct alkalosis before anesthesia. Preoperatively, a significant fall in blood pressure with aldosterone receptor antagonists predicts a successful outcome after adrenalectomy. Response to adrenalectomy is also influenced by the duration and severity of hypertension and by the presence of histologic changes in the kidney. Age greater than 50 years, male sex, and the presence of multiple nodules within the adrenal is also associated with a poor response to surgery.

7 Management of idiopathic adrenal hyperplasia is medical because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy. Idiopathic adrenal hyperplasia is treated with spironolactone or with the newer aldosterone antagonist eplerenone. Other potassium-sparing diuretics may be used including triamterene and amiloride. Treatment of glucocorticoid-suppressible hyperaldosteronism includes dexamethasone 0.5 to 1.0 mg daily. Glucocorticoids are used in small doses to avoid Cushing syndrome.

Congenital Adrenal Hyperplasia

8 The congenital adrenal hyperplasia syndromes are autosomal recessive conditions resulting from inherited defects of one or several of the enzymes necessary for cortisol biosynthesis (Fig. 77.8). Cortisol deficiency leads to ACTH overproduction and

FIGURE 77.7. Aldosteronoma within right adrenal gland shown in Figure 77.6.

secondary hyperplasia of the adrenal cortex with shunting of cortisol precursors into adrenal androgen pathways. Peripheral tissues convert the excess adrenal androgens to testosterone, which causes virilization of the patient.

Most cases (>90%) of congenital adrenal hyperplasia are secondary to deficiency of 21-hydroxylase (CYP21A2) resulting from mutation of the gene on the short arm of chromosome 6. Two forms of this deficiency are recognized: partial or complete. The complete form is characterized by androgen excess at birth, with virilization, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. The partial form is characterized by virilization only and may present in adolescence or adulthood.

FIGURE 77.8. Schematic representation of the mechanism underlying congenital adrenal hyperplasias. Enzymatic defects in the adrenal gland prevent normal production of cortisol with resulting loss of negative feedback to the hypothalamus and pituitary. Chronic adrenocorticotrophic hormone stimulation of the adrenal gland shunts steroid precursors through androgenic and mineralocorticoid pathways, leading to the overproduction of androgens and mineralocorticoids. The most common deficiencies are CYP21A2 (21-hydroxylase), CYP11B1 (11 β -hydroxylase), and 3- β -HSD (3- β -hydroxysteroid dehydrogenase).

Of the remaining causes of congenital adrenal hyperplasia, 11-beta-hydroxylase deficiency (CYP11B1) is the second most common cause, followed by 3-beta-hydroxydehydrogenase and 17-hydroxylase (CYP17) deficiency. Congenital lipoid adrenal hyperplasia is the most severe form of congenital adrenal hyperplasia and is often fatal (Table 77.4).

Signs and Symptoms. Prenatal adrenal virilization in females produces ambiguous external genitalia (female pseudohermaphroditism). The ovaries, fallopian tubes, and uterus develop normally, and patients are fertile. Postnatal congenital adrenal hyperplasia causes virilization of females and precocious puberty of males. Females develop hirsutism, polycystic ovaries, and irregular menses. Male patients exhibit secondary sexual characteristics by age 2 or 3 years. Fertility is often impaired. Both sexes experience rapid somatic growth and short stature. Virilization, salt wasting, and hyperpigmentation are variably present with the non-21-hydroxylase forms of congenital adrenal hyperplasias.

Diagnosis. Elevated plasma 17-hydroxyprogesterone is the most characteristic abnormality found in 21-hydroxylase deficiency. Both plasma cortisol and 24-hour free urinary cortisol excretion are variably reduced. Diagnosis of other forms of the disease involves demonstration of elevated levels of enzyme substrate: corticosterone and 11-deoxycortisol for 11-beta hydroxylase; dehydroepiandrosterone and 17 delta-5 hydroxypregnenolone for 3-beta hydroxydehydrogenase; and deoxycorticosterone and corticosterone for 17 beta-hydroxylase deficiency (Table 77.4).

Treatment. The treatment of 21-hydroxylase deficiency is glucocorticoid and mineralocorticoid replacement. Clinical management is often complicated by inadequately treated hyperandrogenism or iatrogenic hypercortisolism, or both. New treatment approaches under investigation include combination therapy to block androgen action and inhibit estrogen production, and bilateral adrenalectomy in the most severely affected patients. Female patients with ambiguous genitalia may require surgical correction as infants. Treatment of congenital adrenal hyperplasias caused by other enzyme deficiencies includes steroid and electrolyte replacement and surgical correction of the external genitalia in affected female infants.

Virilizing and Feminizing Adrenal Tumors

Excess production of adrenal androgens by an adrenal adenoma or carcinoma can produce virilizing features either alone or more commonly in addition to Cushing syndrome. Development of an adrenal virilizing tumor in women causes hirsutism and masculinization. Males with these tumors may present late with signs and symptoms of tumor enlargement or distant metastases develop. Virilizing tumors secrete androgen

precursor, dehydroepiandrosterone, which can be measured either directly in plasma or in urine as a 17-ketosteroid. Feminizing adrenal neoplasms are extremely rare. Abdominal CT is subsequently used to localize the lesion. Resection of tumor and involved adrenal gland is the primary treatment for patients with adrenal virilizing tumors. Tumor recurrence is heralded by return of virilization or by detection of increased 17-ketosteroids in the urine. Tumor debulking or inhibition of steroidogenesis with aminoglutethimide or mitotane may be useful in controlling signs and symptoms in patients with metastatic disease.

Adrenocortical Carcinoma

9 Adrenocortical carcinoma is a rare malignancy with an estimated incidence of 0.5 to 2 cases per million per year. Presentation peaks in the first and fifth decades of life. The prevalence is higher in females than in males (1.4 to 2:1). The cause of adrenocortical carcinoma is unknown, although somatic mutations in P53 and inheritance of this tumor in patients with germline mutations in P53 (Li Fraumeni syndrome) implicate this tumor suppressor gene in its pathogenesis.

10 Signs and Symptoms. Adrenocortical carcinoma is a very aggressive malignancy, and most patients (up to 75%) present with locoregionally advanced or distant disease. Syndromes of adrenal hormone overproduction are frequent (up to 60%) and may include hypercortisolism, hyperaldosteronism, or virilization. Patients with rapidly progressive Cushing syndrome or mixed presentations with signs of both Cushing syndrome and virilization should be suspected of having adrenocortical carcinoma. Nonfunctioning adrenocortical carcinomas present most commonly as abdominal pain or mass with vague symptoms of nausea, weight loss, and fatigue.

Diagnosis. Patients with suspected adrenocortical carcinoma should have biochemical testing to identify hormone overproduction followed by staging investigations including cross-sectional imaging and bone scans. Contrast-enhanced CT of the abdomen and chest is important to preoperatively diagnose local tumor invasion and metastatic lesions as well as to confirm a functioning contralateral kidney (Fig. 77.9). In the absence of distant metastases or local invasion, preoperative distinction between large adenomas and carcinomas can be difficult, although large (>6 cm) adrenal masses that extend

FIGURE 77.9. Computed tomography scan of right adrenocortical carcinoma showing invasion of liver and inferior vena cava. Note that a contralateral kidney is present and functioning.

to nearby structures on CT scanning should be approached as carcinomas. Biopsy of adrenal lesions suspected of being adrenocortical carcinoma is unnecessary and should be avoided. The risk of seeding and the inability of histologic examination to distinguish between adenoma and carcinoma make biopsy useless and potentially harmful. Biopsy of extraadrenal lesions may be performed to confirm metastatic disease.

A definitive diagnosis of adrenocortical carcinoma requires pathologic demonstration of tumor invasion to adjacent organs or spread to lymph nodes or distant sites. Practically, any adrenal neoplasm larger than 6 cm or weighing more than 100 g should be considered malignant. Histologic features of tumor necrosis, hemorrhage, and local invasion are gross pathologic evidence of carcinoma, while cells with large, hyperchromatic nuclei and more than 20 mitoses per high-power field suggest malignancy.

Treatment. Surgical resection is the mainstay of treatment for all stages of adrenocortical carcinoma. Complete resection of locally confined tumor is the only chance for cure from adrenocortical carcinoma. However, distant or local spread is evident in 65% of cases at presentation, and a few patients are resectable with curative intent. Recurrence rates after surgery range from 38% to 85%, depending on stage at presentation (Table 77.5).

Many patients with adrenocortical carcinoma present with metastatic disease, involving the lung, lymph nodes, liver, or bone. Resection or surgical debulking of locally advanced or metastatic lesions may provide symptomatic relief for select patients, especially those with low-grade, slow-growing, hormonally productive cancers. Symptomatic recurrent or metastatic disease is best treated by resection when feasible.

Chemotherapy for adrenocortical carcinoma usually includes mitotane, although no controlled studies have established its efficacy in this disease. Partial responses to mitotane occur in less than a third of patients, and survival is unchanged. Adjuvant chemotherapy with mitotane after complete resection

TABLE 77.5

STAGING

AMERICAN JOINT COMMITTEE ON CANCER STAGING OF ADRENOCORTICAL CARCINOMA, WITH 5-YEAR SURVIVAL RATES

■ STAGE	■ CRITERIA	
Tumor		
T1	Tumor <5 cm, no invasion	
T2	Tumor >5 cm, no invasion	
T3	Tumor with invasion to fat	
T4	Tumor with organ invasion	
Lymph nodes		
N0	No lymph node metastasis	
N1	Lymph node metastasis present	
Metastasis		
M0	No distant metastasis	
M1	Distant metastasis present	
Stage Group	TNM	5-Year Survival Rate
I	T1 (<5 cm) N0M0	30%–45%
II	T2 (>5 cm) N0M0	12%–57%
III	T1–2, N1, M0	5%–18%

IV	Any T, any N, M1	0
	T3–4N1M0	

for adrenocortical carcinoma is unproven and toxic so that many oncologists reserve its use for recurrent, unresectable, or metastatic disease. Cisplatin in combination with mitotane or doxorubicin and 5-fluoruracil has been applied in metastatic disease with partial responses noted.

The prognosis of adrenocortical carcinoma is poor. Median survival following diagnosis for all patients is approximately 18 months. Overall survival following resection for all stages of adrenocortical cancer is 15% to 47% at 5 years. Stage-specific 5-year survival is 30% to 45% for stage I, 12% to 57% for stage II, 5% to 18% for stage III, and 0 for stage IV disease.

DISEASES OF THE ADRENAL MEDULLA

Pheochromocytoma

Pheochromocytomas are functional adrenal tumors that arise from neuroectodermal cells of the adrenal medulla or in certain extraadrenal sites. These tumors are uncommon, occurring in 0.005% to 0.1% of persons, but occur with increased frequency in hypertensive populations (0.2% incidence) and in heritable endocrine tumor syndromes. The peak incidence of pheochromocytoma occurs during the fourth and fifth decades of life, and men and women are affected about equally. The *rule of tens* is a useful way to characterize pheochromocytoma: Tumors are bilateral in 10% of cases, extraadrenal in 10%, familial in 10%, multicentric in 10%, and malignant in 10%, and occur in children in 10% of cases.

Approximately 10% of pheochromocytomas are extraadrenal, although most (98%) are still located within the abdomen. Extraadrenal pheochromocytomas can occur at any site in the abdomen where chromaffin tissue is located and have been found in the paravertebral ganglia, the organ of Zuckerkandl, and the urinary bladder. Clues to the presence of extraadrenal pheochromocytoma are predominance of norepinephrine because extraadrenal sites lack the enzyme necessary to convert norepinephrine to epinephrine.

Familial pheochromocytoma is a component of two autosomal dominant syndromes: von Hippel-Lindau syndrome and multiple endocrine neoplasia II (MEN2). Patients with von Hippel-Lindau syndrome have pheochromocytoma (usually bilateral), retinal angiomas, cerebellar hemangioblastoma, epididymal cystadenoma, renal and pancreatic cysts, and renal cell carcinoma. Patients with MEN2A develop pheochromocytoma (usually bilateral), medullary carcinoma of the thyroid (MTC), and primary parathyroid hyperplasia. Patients with MEN2B develop pheochromocytoma (usually bilateral), MTC, mucosal neuromas, and intestinal ganglioneuromatosis, and have a characteristic marfanoid body habitus. Pheochromocytoma also occurs in neurofibromatosis type 1 and familial paraganglioma. The frequency of pheochromocytoma in these disorders is 10% to 20% in von Hippel-Lindau syndrome, 50% in MEN2, and 0.1% to 5.7% with neurofibromatosis type 1.

In some families, patients with pheochromocytomas have no other clinical abnormalities, suggesting the existence of a separate disease limited to the formation of adrenal medullary tumors. In a study of three generations of an affected kindred, a novel mutation was found in the von Hippel-Lindau gene even though there were no other clinical manifestations of this disorder. Patients with bilateral pheochromocytoma, young patients with pheochromocytoma, and patients with paraganglioma should be screened for MEN2 and von Hippel-Lindau syndrome.

The etiology and pathogenesis of pheochromocytoma is unknown. A genetic component seems certain because pheochromocytoma occurs not only as a part of familial syndromes but also as an isolated disorder because of mutation in the RET gene or the MEN2 gene. Familial pheochromocytoma

as well as sporadic pheochromocytoma occurs also with mutations in the succinate dehydrogenase complex, subunit B, iron sulfur protein (SDHB). Either germline or somatic mutations in the SDHD gene are another cause of pheochromocytoma.

Signs and Symptoms. Symptoms of pheochromocytoma are attributable to the effects of excessive circulating catecholamines on target tissues (Table 77.3). The classic triad of symptoms in patients with a pheochromocytoma is episodic headache, sweating, and tachycardia. Hypertension is common with pheochromocytoma and is sustained in roughly half of patients, is paroxysmal in one third, and is absent in one fifth. Orthostatic hypotension results from diminished plasma volume and blunted autonomic reflexes. Other symptoms include palpitations, anxiety, and tremulousness. Cardiovascular sequelae include myocardial infarction, cardiac dysrhythmias, and stroke. Gastrointestinal motility is also impaired. Asymptomatic patients with functioning tumors are rare, and non-functioning tumors are distinctly uncommon. Sudden death has been reported in patients with pheochromocytoma who have undergone surgical procedures or childbirth.

Diagnosis. Elevation of catecholamines and their metabolites in either urine or blood is essential for the diagnosis of pheochromocytoma. Either a 24-hour urine collection for catecholamines and their metabolites (metanephrines) or plasma-fractionated metanephrines can be used to make the diagnosis. Urine catecholamines/metanephrines is the most reliable test with a sensitivity and specificity of 98%. Plasma fractionated metanephrines is similarly sensitive (99%), but lacks specificity (85%). Accordingly, plasma-fractionated metanephrines should be reserved for patients with a high pretest probability for pheochromocytoma—adrenal incidentalomas, classic symptoms, family history of genetic syndromes associated with pheochromocytoma (MEN, etc.)—whereas urine catecholamines/metanephrines is useful as a screening tests for patients who are less likely to have a pheochromocytoma. Measurement of plasma catecholamines is not as useful in distinguishing patients with pheochromocytoma from those with essential hypertension. Measurement of plasma chromogranin A is nonspecific and a poor diagnostic but potentially helpful confirmatory test.

Many medications alter or interfere with measurement of either plasma or urine catecholamines. Such medications should be discontinued to ensure accurate testing. These drugs include acetaminophen, labetalol, clonidine withdrawal, tricyclic antidepressants, antipsychotics, and ethanol. To control blood pressure, other antihypertensives such as calcium channel blockers may be substituted.

In normotensive or mildly hypertensive patients with elevated plasma catecholamine levels (1,000–2,000 pg/mL), a clonidine suppression test may be used to distinguish from pheochromocytoma. An oral 0.3-mg dose of clonidine suppresses centrally mediated release of catecholamines to less than 500 pg/mL within 2 to 3 hours but does not affect release of catecholamines by a pheochromocytoma.

Biochemical confirmation of the diagnosis should be followed by radiologic evaluation to locate the tumor. Pheochromocytomas are best imaged with CT or MRI. Contrast-enhanced CT readily detects tumors 1 cm and larger and has sensitivity of 87% to 100% for pheochromocytoma (Fig. 77.10A). MRI is similarly sensitive, and a T2-weighted image brightness three times greater than liver is highly specific for pheochromocytoma (Fig. 77.10B and C). MRI is useful in suspected malignant pheochromocytoma to evaluate for inferior vena cava thrombus or liver invasion.

Functional nuclear imaging with iodine-131-metaiodobenzylguanidine (131-I MIBG) is a useful adjunct to cross-sectional imaging for pheochromocytoma (Fig. 77.10D). MIBG resembles norepinephrine and is taken up by adrenergic tissues including pheochromocytoma. An MIBG scan can detect

FIGURE 77.10. Imaging of pheochromocytoma (arrows). **A:** Computed tomography scan shows well-circumscribed left adrenal mass. **B:** T2-weighted magnetic resonance imaging shows the mass to be heterogeneously bright consistent with pheochromocytoma. **C** and **D:** Coronal contrast-enhanced MRI and near-simultaneous ¹³¹I-metaiodobenzylguanidine (¹³¹I-MIBG) scanning show location of the pheochromocytoma and relationship to surrounding structures.

tumors not detected by CT or MRI or multiple tumors when CT or MRI is positive. Multi-institutional experience with this technique has demonstrated an overall sensitivity of 77% to 87% and a specificity of 96% to 100%. This test is usually not necessary for sporadic pheochromocytoma unless urinary or plasma catecholamines and metabolites are marginally elevated, or if malignant or extraadrenal pheochromocytoma is suspected. ¹³¹I-MIBG scanning is also useful to screen patients with metastatic pheochromocytoma for high-dose ¹³¹I-MIBG therapy. ¹¹¹In-pentetreotide scintigraphy may also identify pheochromocytoma and can be used therapeutically as with ¹³¹I-MIBG.

Treatment. Surgical resection is the only cure for pheochromocytoma. When the diagnosis of pheochromocytoma has been established and localization studies are completed, preoperative preparation of the patient centers on blood pressure control. Usually 1 to 3 weeks before operation, alpha-adrenergic blockade

is performed first with phenoxybenzamine, starting at 10 mg twice a day and increasing by 10 to 20 mg per day, until blood pressure normalizes. Side effects of alpha blockade include postural hypotension, reflex tachycardia, nasal congestion, and an inability to ejaculate. Preoperative alpha blockade also reverses the relative hypovolemia that is usually present in patients with pheochromocytoma and also prevents severe blood pressure swings during intraoperative manipulation of the tumor. Metoprolol added preoperatively to phenoxybenzamine can achieve a greater degree of sympathetic blockade.

Beta-adrenergic blockade with propranolol added after alpha blockade can manage patients who develop tachycardia or who have inducible cardiac arrhythmias or ischemia. Propranolol may enhance pressor response to endogenous norepinephrine and thus should not be given until adequate alpha blockade has been established. Propranolol can also produce profound bradycardia, myocardial depression, and congestive heart failure. Newer drug regimens to manage hypertension in

pheochromocytoma include selective alpha-1-adrenergic antagonists (terazosin and doxazosin) and calcium channel blockers (nifedipine and nicardipine).

Patients with pheochromocytoma can be expected to have blood pressure volatility and high intravascular volume requirements during and immediately after surgery. Elderly patients or those with a history of heart disease may require pulmonary catheter insertion and arterial line placement for careful monitoring of blood pressure and arterial pH. Anesthetic agents may trigger the release of catecholamines from pheochromocytomas. The anesthetic plane is now considered more important than the choice of agent, and both enflurane and isoflurane have been used successfully. Magnesium administration during surgery is an effective way to control blood pressure in patients with pheochromocytoma. Intraoperative hypertension is best treated with a sodium nitroprusside drip, and cardiac arrhythmias are best managed with short-acting beta-blockers (esmolol) or lidocaine.

Formerly, an anterior approach through either a midline or bilateral subcostal incision was used exclusively to resect pheochromocytomas. Today, CT, MRI, and nuclear scans permit preoperative localization of tumor in 95% or more of cases, so that the surgical approach may be more directed using a laparoscopic approach. Regardless of approach, important common principles include minimal handling of the tumor, early isolation and ligation of the adrenal vein, and avoidance of capsular rupture. Recurrence following resection of benign pheochromocytoma is infrequent, and its presence indicates malignancy.

Recurrent, malignant pheochromocytoma can include locally advanced disease or metastasis to bone, liver, lymph nodes, lungs, and the central nervous system. Treatment of malignant pheochromocytoma involves resection of metastases when feasible and medical control of hypertension. Radiation therapy may be helpful to ameliorate pain from bony metastases. Ablative therapy with ¹³¹I MIBG may also produce partial responses and palliation of hormonal symptoms. Radiofrequency ablation of hepatic and bone metastases can be effective in selected patients. Combination chemotherapy with cyclophosphamide, vincristine, and dacarbazine can also be effective. Overall 5-year survival for patients with malignant pheochromocytoma ranges from 36% to 60%.

Metastasis to the Adrenal Glands

The adrenal glands are frequent sites for metastases from many cancers. Carcinoma of the lung and breast account for most adrenal metastases; however, virtually any cancer including melanoma, lymphoma, and kidney and ovarian carcinoma can spread to the adrenals. Autopsy series of patients with carcinoma show that the adrenal glands are involved in more than 25% of cases. Among cancer patients, 50% to 75% of newly discovered adrenal masses represent metastases. Usually, either a primary site is obvious or widespread disease is apparent. Biopsy of adrenal masses in patients with a history of carcinoma may be performed after pheochromocytoma is excluded. Resection of isolated adrenal metastases in select patients with long disease-free intervals from lung cancer, renal cell carcinoma, and melanoma can be considered, although subsequent extraadrenal disease usually develops. Median survival after complete resection of isolated adrenal metastases from various tumors ranges from 13 to 60 months with actuarial 2- and 5-year survival of 40% to 50% and 20%, respectively.

Incidental Adrenal Mass

Clinically inapparent adrenal masses (also called *adrenal incidentalomas*) have become commonplace over the past 20 years with the increased use of abdominal imaging such as CT and

MRI. The estimated prevalence of incidental adrenal neoplasms varies by population studied and method of detection. Unsuspected adrenal masses are detected by CT in 0.6% to 1.9% of healthy patients, a figure that is somewhat lower than the estimated prevalence of up to 8.7% based on unselected autopsy data. Patients with a prior history of malignancy have a prevalence of adrenal masses of up to 4.4%. Adrenal masses increase in frequency with advancing age, ranging from 3% in midlife to 10% in the elderly. The combination of an aging population and increased application of abdominal imaging promises to create a significant public health challenge.

Over the past 10 years, increased awareness of morbidity associated with subclinical hormone overproduction, as well as the increased availability of minimally invasive laparoscopic adrenalectomy, has resulted in a lower threshold for treatment of adrenal masses. The goal of evaluation is to distinguish and remove those adrenal masses that are functioning or likely to be malignant versus those that are neither and may be observed.

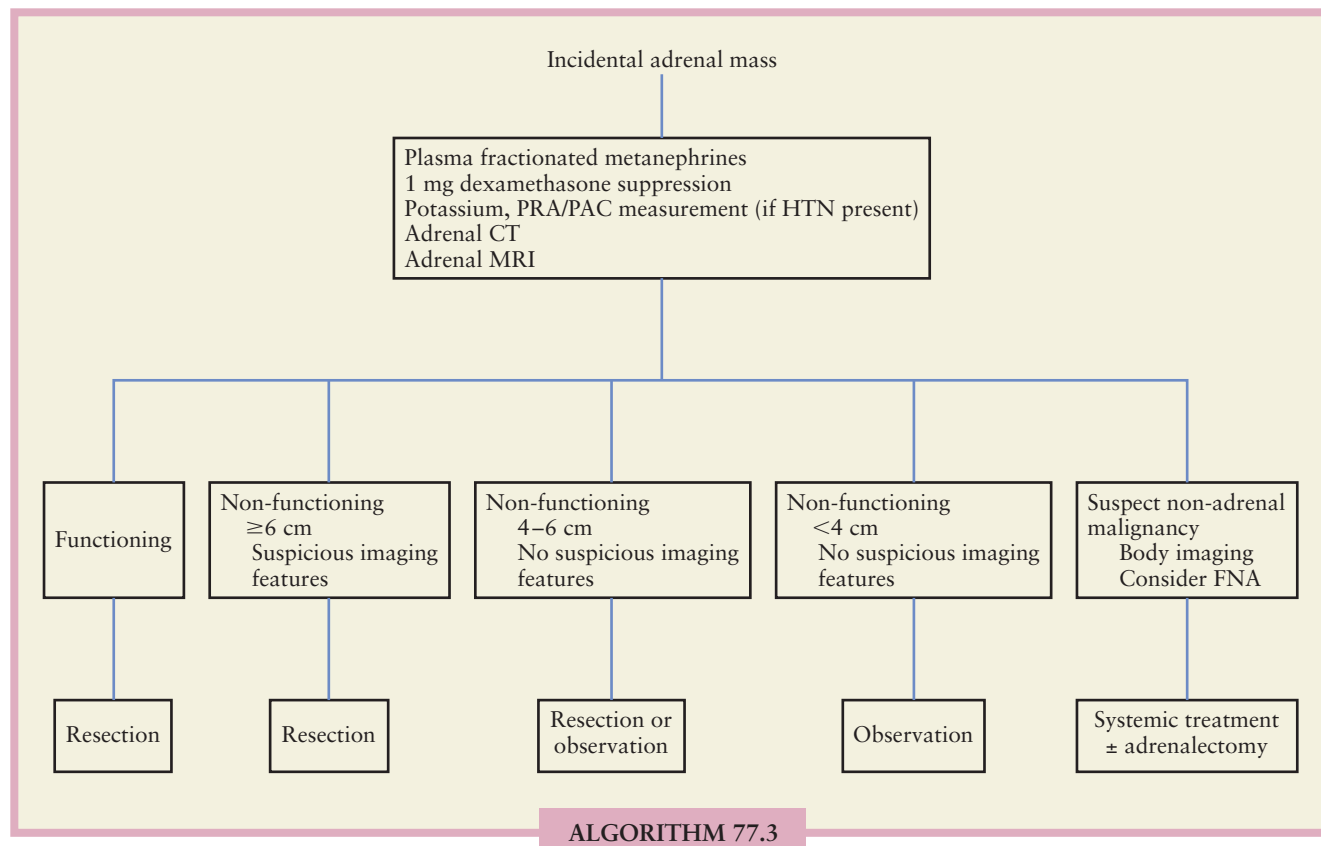

Expectations of the yield for the workup of adrenal masses may be informed by epidemiologic reports and reports of pathologic findings in resected incidentalomas. Epidemiologic data indicate that up to 6.5% of incidentalomas are pheochromocytoma, 7% produce aldosterone, 0.035% produce cortisol, and 0.06% are carcinoma. A recent review of 44 reports describing more than 3,000 such cases reported that 41% were cortical adenomas, 19% were metastases from other primary cancers, 10% were adrenocortical carcinomas, and 8% were pheochromocytomas, with the remainder including myelolipomas and cysts.

Diagnosis. The evaluation of incidental adrenal masses, previously considered controversial, can now be standardized. Two simple questions must be answered: Is it functional? Is it malignant? The diagnostic approach should proceed to answer these questions sequentially (Table 77.6). Current opinion is that all asymptomatic patients with adrenal masses should be screened for pheochromocytoma, hypercortisolism, and hyperaldosteronism (Algorithm 77.3).

All patients require a complete history and physical examination, biochemical evaluation of pertinent hormones, and select imaging studies. Attention must be paid to episodes of hypertension, tachycardia, and anxiety that suggest pheochromocytoma. Physical findings such as muscle wasting, purple striae, hirsutism, and gynecomastia may suggest either Cushing syndrome or a virilizing tumor. Secondary metastases from underlying malignancy must be considered and evaluated with appropriate history, physical examination, and select tests including mammograms in women and chest radiography in all patients, especially smokers.

Biochemical testing should routinely exclude pheochromocytoma, hypercortisolism, and hyperaldosteronism. Pheochromocytoma is evaluated either by 24-hour urine collection for catecholamines, metanephrines, and 3-methoxy-4-hydroxymandelic acid, or by plasma-fractionated metanephrines. Subclinical or clinically apparent Cushing syndrome is best evaluated with the overnight 1-mg dexamethasone suppression test. Hyperaldosteronism is best assessed by concurrent measurement of serum or plasma aldosterone and PRA.

Imaging studies usually include cross-sectional imaging with either CT or MRI. CT is the best test for identifying and characterizing most adrenal masses. Using a fast scanner and 1-m scanning intervals, both adrenal glands can be identified in 97% to 99% of patients and lesions as small as 5 mm can be readily identified. Currently, attenuation values expressed in Hounsfield units (HU) have better performance than size or other criteria to differentiate adenomas from adrenal malignancy and nonadenomas such as pheochromocytoma. Adenomas are usually lipid rich and have attenuation values less than 18 HU on unenhanced CT, a threshold with high sensitivity and specificity (85%–95% and 93%–100%, respectively).

ALGORITHM 77.3. Diagnosis and management of the incidental adrenal mass. PRA, plasma renin activity; PAC, plasma aldosterone concentration; HTN, hypertension; CT, computed tomography; MRI, magnetic resonance imaging; FNA, fine-needle aspiration.

Generally, further workup is unnecessary when an adrenal lesion has an attenuation of less than 10 HU, suggesting lipid-rich adrenal adenoma. A notable exception is lipid-poor adenoma, which has higher HU density. In these cases, rapid washout of intravenous contrast suggests an adenoma. Using a 10- to 15-minute delayed enhanced CT, a washout value of

50% to 60% of the initial enhancement is used to distinguish adenoma from nonadenoma.

MRI can differentiate adenomas, metastases and pheochromocytomas, although the best MRI technique for evaluating adrenal masses is complex and controversial. Adenomas usually show a loss in signal intensity on chemical shift MRI

TABLE 77.6

DIAGNOSIS

SUMMARY OF TESTS FOR EVALUATION OF INCIDENTAL ADRENAL MASS

■ QUESTION	■ BEST TEST	■ ALTERNATIVE TEST	■ DIAGNOSIS
Is it functioning?	Plasma fractionated metanephrines	24-h urine for catecholamines, metanephrines, VMA	Pheochromocytoma
	- mg dexamethasone suppression test	24-h urine for cortisol	Hypercortisolism
	Serum potassium	24-h urine for potassium	Hyperaldosteronism
	Plasma renin/plasma aldosterone ratio		
Is it malignant?	Computed tomography	Magnetic resonance imaging	Cortical adenoma
	Fine-needle aspiration		Adrenocortical Carcinoma
			Pheochromocytoma
			Myelolipoma
			Cyst
			Metastasis

because of high lipid content. Malignant masses tend to be bright on T2-weighted images because of higher fluid content. Secondary metastases to the adrenal are hypointense to liver on T1-weighted images and are brighter than liver on T2-weighted images. Metastases also typically show strong contrast enhancement. Pheochromocytomas most often have low lipid content and high water content, giving low T1 signal intensities and very bright T2 signal intensities. Comparison of the adrenal mass to liver and spleen intensities on various sequences adds to specificity and sensitivity of the test.

Masses that appear cystic may be aspirated under CT guidance. Fine-needle aspiration biopsy may be of value in patients with known extraadrenal malignancy; however, it is not indicated in the evaluation of primary adrenal neoplasms and is contraindicated if pheochromocytoma is suspected.

Treatment. Resection is indicated for all functioning adrenal incidentalomas and those suspected of harboring primary adrenal cancer. Size cutoff for resecting adrenal incidentalomas has drifted to include smaller and smaller lesions. The prevalence of primary adrenal carcinoma in adrenal incidentalomas is related to mass size. The risk of primary adrenal carcinoma is less than 2% in lesions smaller than 4 cm whereas the incidence rises to 25% for lesions larger than 6 cm. Lesions larger than 6 cm and smaller lesions with suspicious criteria on imaging should be resected. Lesions smaller than 4 cm with benign imaging characteristics should be followed. For lesions between 4 and 6 cm, either resection or observation is acceptable. Decisions should not be based on size alone, but also on imaging characteristics including CT attenuation values. Resection of secondary adrenal malignancy is not generally recommended except for highly select patients.

Adrenal Insufficiency

Adrenal insufficiency reflects inadequate glucocorticoid and mineralocorticoid production by the adrenals, either secondary to suppression of the HPA axis or by destruction or removal of the adrenal glands. The most common causes of primary adrenal insufficiency are autoimmune adrenalitis, infection, and gland replacement with metastatic disease. Chronic exogenous steroid use with HPA suppression and surgical resection of adrenal glands are important causes of secondary adrenal insufficiency.

Clinical signs and symptoms usually do not become manifest until at least 90% of the gland is destroyed. Adrenal insufficiency usually occurs gradually unless the patient experiences stress, which may precipitate acute crisis.

Signs and Symptoms. Acute adrenal insufficiency usually manifests as shock in a patient with undiagnosed chronic adrenal insufficiency who has been subjected to physiologic stress. Similarly, patients with established adrenal insufficiency caused by exogenous steroid use may experience crisis if they do not increase glucocorticoid replacement during times of stress or illness. Symptoms of adrenal insufficiency reflect glucocorticoid and mineralocorticoid deficiencies. Signs and symptoms of acute insufficiency include fever, nausea, vomiting, refractory hypotension, and lethargy (Table 77.7). Acute adrenal insufficiency is a medical emergency and should be suspected in stressed patients with a history of either adrenal insufficiency or exogenous steroid use. Chronic adrenal insufficiency presents more subtly, with fatigue, weight loss, anorexia, nausea and vomiting, abdominal pain, and diarrhea.

Diagnosis. Laboratory findings of adrenal insufficiency include hyponatremia, hyperkalemia, azotemia, and fasting or reactive hypoglycemia. Hypercalcemia may also be present. The rapid ACTH stimulation test is the best test for both acute and chronic adrenal insufficiency. Synthetic ACTH (250 μ g) is

TABLE 77.7

DIAGNOSIS

SYMPTOMS AND SIGNS OF ACUTE ADRENAL INSUFFICIENCY

SYMPTOMS

- Lethargy
- Confusion or disorientation
- Nausea and vomiting
- Abdominal pain

SIGNS

- Hypotension
- Hyponatremia, hyperkalemia, azotemia,
- Hypoglycemia
- Fever
- Anemia

administered intravenously, and plasma cortisol levels are measured 30 and 60 minutes later. Normal peak cortisol response should exceed 20 μ g/dL. Measurement of ACTH by immuno-radiometric assay (IRMA) is then used to distinguish primary from secondary and tertiary adrenal insufficiency. High plasma concentration of ACTH (>200 pg/dL) and low plasma cortisol (<10 mg/dL) are diagnostic of primary adrenal insufficiency. Low levels of plasma ACTH indicate secondary (pituitary) or tertiary (hypothalamic) adrenal insufficiency.

Treatment. Acute adrenal insufficiency is based on clinical suspicion before laboratory confirmation is available. Intravenous volume replacement with isotonic fluids and immediate intravenous steroid replacement therapy with 4 mg dexamethasone is essential. A rapid ACTH stimulation test is then performed to establish the diagnosis of adrenal insufficiency after resuscitation and corticosteroid replacement. Hydrocortisone acetate is detected in laboratory measurement for cortisol so dexamethasone should be used for replacement of glucocorticoid function until ACTH testing is complete. Thereafter, 100 mg of hydrocortisone is administered intravenously every 6 to 8 hours and is tapered to standard replacement doses as the patient's condition stabilizes. Mineralocorticoid replacement is not required until oral intake resumes. Chronic adrenal insufficiency requires both corticosteroid and mineralocorticoid replacement. Usual daily dosing is 12 mg/m² of hydrocortisone and 0.05 to 0.10 mg fludrocortisone.

Patients who have known adrenal insufficiency or who have received supraphysiologic doses of corticosteroid for at least 1 week in the year preceding surgery should receive perioperative stress-dose corticosteroids. Administration of 100 mg hydrocortisone the morning of major surgery followed by 100 mg of hydrocortisone every 8 hours during the perioperative 24 hours is usually more than sufficient. Steroids can be rapidly tapered to replacement levels as the patient's condition permits.

ADRENALECTOMY

Surgical approaches to the adrenal glands include the laparoscopic approach, the anterior transabdominal approach, and less commonly, the combined thoracoabdominal approach or posterior retroperitoneal approach. Either adrenal gland can be removed using any of these approaches. The choice of approach depends on the suspected pathology, the size of the adrenal lesion, and the expertise of the surgeon. Small benign-appearing tumors that are localized with confidence by imaging studies are resected using a laparoscopic or posterior approach. Posterior retroperitoneal adrenalectomy, once the most common method of adrenalectomy, is less commonly used since most lesions amenable to this approach can be

removed laparoscopically. Large adrenal masses and those that may harbor malignancy should be resected using an anterior approach to adequately explore the entire abdomen and gain sufficient exposure for safe resection. Very large adrenocortical carcinomas may require a thoracoabdominal approach for en bloc resection with involved adjacent structures. Recently, a retroperitoneal laparoscopic approach has been advocated as an alternative method for small tumors, particularly for patients with prior abdominal surgery.

Laparoscopic Adrenalectomy

Laparoscopic adrenalectomy is now the preferred approach to most small, benign adrenal lesions including functioning and nonfunctioning adenomas and pheochromocytomas. Enthusiasm for the laparoscopic approach is based on the expectation of decreased postoperative pain, faster rehabilitation, and fewer complications. Numerous studies have shown the effi-

cacy and safety of this procedure for tumors up to 6 cm. Larger lesions can be approached by experienced surgeons in select circumstances. It is important that expertise in open adrenalectomy is absolutely necessary for the laparoscopic surgeon to convert to an open procedure and promptly rectify any intraoperative laparoscopic complications.

Laparoscopic adrenalectomy begins with induction of general anesthesia, placement of a urinary catheter and orogastric tube, and positioning of the patient in the lateral decubitus position with the affected side up. Exposure is facilitated by extension of the operating table at the patient's waist. A total of three or four intraperitoneal ports (one camera, one retractor particularly for the right side, and two working ports) are placed at least 5 cm apart in a transverse line from the lateral edge of the rectus sheath to the midaxillary line between the costal margin and iliac crest (Fig. 77.11A). Four-quadrant exploration of the peritoneal cavity is first performed with the videoscope through the medialmost port, and the videoscope is then transferred to the middle port. A retractor is placed

FIGURE 77.11. Incisions for right adrenalectomy. Shown are typical incisions for (A) laparoscopic approach, (B) open anterior approach, (C) thoracoabdominal approach, (D) posterior open approach, and (E) posterior laparoscopic approach. Incisions for left adrenalectomy are positioned opposite. (continued)

FIGURE 77.11. (Continued)

through the medialmost port to retract the viscera medially. Operating instruments are alternately placed within the abdomen through the lateral ports.

Laparoscopic adrenalectomy proceeds similar to the open anterior approach. Right adrenalectomy begins with mobilization of the liver to open the retroperitoneum and allow retraction of the right lobe anteriorly and medially using the most medial port. The adrenal gland is then identified posterolateral to the inferior vena cava and superior to the kidney. Dissection usually begins by developing the plane between right adrenal and inferior vena cava using careful blunt dissection, with small vessels sequentially coagulated using electrocautery or harmonic energy. The right adrenal vein is identified, carefully dissected, and then doubly clipped and divided (Fig. 77.12A). Dissection then continues circumferentially around the gland with additional small vessels coagulated or clipped. The adrenal gland subsequently is placed in a bag and removed through an expanded port.

Left adrenalectomy is performed with mirror-image patient and port site orientation as right adrenalectomy. After port placement, dissection begins with mobilization of the splenic flexure of the colon and spleen from the left retroperitoneum. Subsequent medial retraction of the spleen, tail of the pancreas, and stomach is accomplished with the fan or similar retractor if necessary. Often after full mobilization, no retractor is necessary, and thus only three ports are needed. The left adrenal gland is identified in perinephric fat at the superior renal pole. Intraoperative laparoscopic ultrasound can be useful for this on the left side, particularly in Cushing syndrome with the associated increased truncal fat. Once identified, left adrenal gland dissection proceeds circumferentially around the gland, with identification, ligation, and division of the left adrenal vein at the inferiormost aspect of the dissection (Fig. 77.12B). Care is needed to identify and avoid the inferior phrenic vein, which courses along the medial aspect of the left adrenal gland. Following circumferential dissection, the gland is removed.

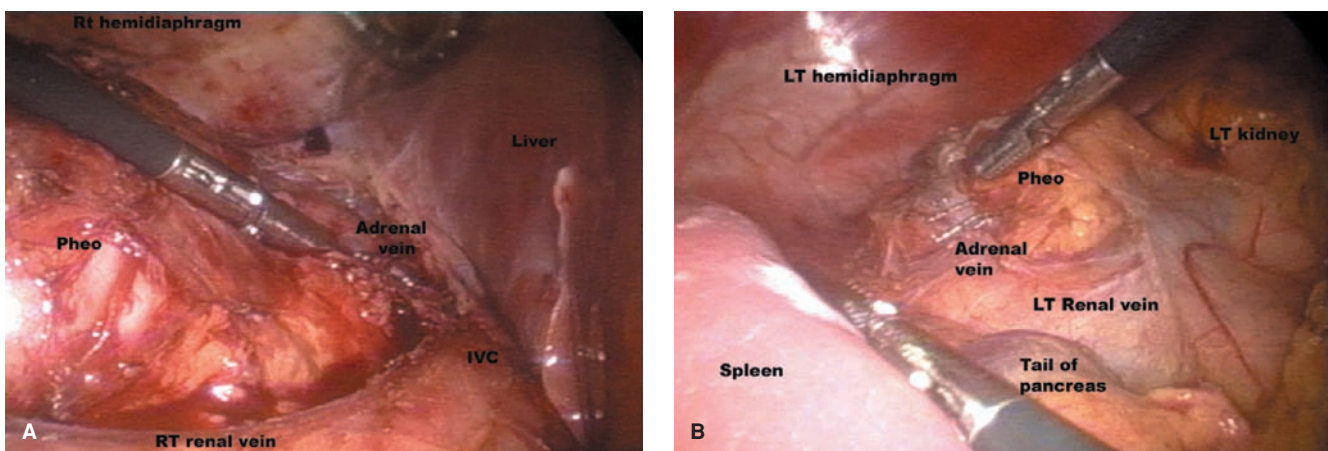

FIGURE 77.12. Laparoscopic adrenalectomy. Shown are intraoperative views of exposed right (A) and left (B) adrenal pheochromocytomas (pheo) in a patient with multiple endocrine neoplasia (MEN)-2 A. Note clips on each adrenal vein. IVC, inferior vena cava.

Anterior Approach

Anterior open adrenalectomy begins with positioning the patient in reverse Trendelenburg position with elevation of the right flank. An ipsilateral or bilateral subcostal incision allows access to either adrenal and facilitates exploration of the abdomen (Fig. 77.11B). The abdomen is opened and explored for evidence of metastatic disease, including biopsy or excision of suspicious lesions. Resection of the right adrenal gland proceeds with full mobilization and anteromedial retraction of the right hepatic lobe (Fig. 77.13A). It is important to fully expose the retrohepatic inferior vena cava. To uncover the inferior vena cava, the right kidney and the right adrenal gland, the hepatic flexure, and transverse colon are retracted inferiorly, usually without need for extensive mobilization. A Kocher maneuver of the duodenum is seldom necessary as the adrenal gland is superior to this area. The retroperitoneal space is entered behind the liver to expose the adrenal gland. Dissection of the gland proceeds from its inferomedial aspect, where small feeding arteries are individually clipped and divided. The vena cava is carefully dissected along its lateral border, which allows identification of the right adrenal vein where it drains directly into the inferior vena cava from the anterior aspect of the adrenal gland. The adrenal vein is ligated and divided close to the vena cava. If necessary because of hemodynamic changes during an operation for a pheochromocytoma, the adrenal vein is identified and ligated early to avoid catecholamine surges and blood pressure fluctuations during manipulation of the gland. Once the adrenal vein is ligated, arterial feeding vessels are clipped and divided sequentially, beginning at the superolateral aspect of the gland and continuing medially.

Resection of the left adrenal gland requires mobilization of the spleen, tail of pancreas, and left colon. The left colon is freed from its peritoneal attachments and is reflected inferiorly. The spleen is then delivered from the left upper quadrant medially, and the splenocolic ligament is divided. The spleen, stomach, and pancreatic tail are retracted medially en bloc to expose the left kidney and adrenal (Fig. 77.13B). The left adrenal vein is ligated and divided at its junction with the left renal vein. The gland is dissected, and the arterial vessels are ligated and divided sequentially, beginning at the superolateral aspect of the gland and continuing medially.

Thoracoabdominal Approach

The thoracoabdominal approach is used for large adrenal lesions with invasion of surrounding structures including the liver and

diaphragm on the right side, and the spleen, pancreatic tail, stomach, and diaphragm on the left. The patient is positioned with the ipsilateral flank raised and arm extended cephalad. Incision is made in the 10th or 11th intercostal space beginning at the posterior axillary line and is extended toward the midline of the abdomen (Fig. 77.11C). Retractors are placed, and subsequent adrenalectomy is performed as for the anterior approach.

Posterior Approach

With the advent of laparoscopic adrenalectomy, the posterior approach is infrequently used. When laparoscopic adrenalectomy is not an option, typically because of extensive prior transperitoneal operations, the posterior approach is better tolerated and allows faster postoperative recovery compared with the anterior approach. A posterior approach becomes increasingly more difficult as tumor size increases and is not recommended for excision of large pheochromocytomas, adrenal tumors greater than 6 cm, or adrenal carcinoma.

The patient is placed prone on the operating table and flexed at the waist, which allows the abdominal contents to fall away from the retroperitoneum. The incision is made from the midline at the 10th rib and is extended inferolaterally to the superior border of the posterior iliac crest (Fig. 77.11D). Dissection proceeds through the subcutaneous fat and latissimus dorsi muscle to the lumbodorsal fascia. This fascia is incised longitudinally, and the underlying sacrospinalis muscle. The sacrospinalis muscle is retracted medially, and the 12th rib and vascular bundle are resected as far medially as possible. The 12th intercostal nerve is preserved and gently retracted superiorly. The retroperitoneum is entered and the diaphragm is bluntly elevated from the Gerota fascia, the pleura are separated from the diaphragm, and the diaphragm is then divided. The Gerota fascia is incised, and the kidney is retracted inferiorly to expose the adrenal gland. The arterial blood supply is controlled first by clipping and ligating numerous arterial vessels, which course posteriorly. The adrenal vein, located deep to the arteries, is ligated as it is encountered. On the right, the adrenal vein exits from the anterior aspect of the gland and courses to the inferior vena cava. Once the adrenal vein is divided, the gland is then freed circumferentially from its lateral to medial aspect. The inferior border of the gland is dissected last to maintain attachment to the kidney and allow inferior retraction of the gland. The procedure is completed by repair of the diaphragm and any incidental pleural defects, reapproximation of the lumbodorsal fascia, and closure of the skin.

FIGURE 77.13. Anterior approach to right (A) and left (B) adrenalectomy. Note position of phrenic vein in relationship to the left adrenal vein and tumor.

Posterior Retroperitoneal Laparoscopic Adrenalectomy

Posterior retroperitoneal laparoscopic adrenalectomy, also known as posterior retroperitoneoscopic adrenalectomy, maintains the advantages of a laparoscopic approach while avoiding the abdominal cavity. This approach is ideal for patients with prior abdominal surgery or for bilateral adrenalectomy as both adrenal glands can be removed without repositioning the patient.

Posterior retroperitoneal laparoscopic adrenalectomy begins with placing the patient in the prone jackknife position on a spinal table allowing the abdominal contents to hang forward. The hips and knees are positioned at 90-degree angles to the spine and femur and carefully padded. The first port is placed just below the tip of the 12th rib; after the incision is made, the retroperitoneal space is entered sharply, a space is created bluntly with the index finger, and a blunt 10-mm trocar is placed. A second medial 10-mm trocar is placed along the paraspinous muscle at a 45-degree angle toward the adrenal gland. A lateral 5-mm port is placed 5 cm lateral to the first port in a similar fashion (Fig 77.11E). Pneumoretroperitoneum to 20 to 24 mm Hg is created with CO₂ to create an adequate working space. The videoscope is transferred from the initial middle port to the medial port to complete the dissection. The retroperitoneal space beneath the diaphragm is created bluntly and sharply. The superior border of the kidney is immediately identified, and the Gerota fascia is entered. The upper pole of the kidney is retracted caudally, and the tissue superior to the kidney that contains the adrenal gland is completely separated from the kidney. The medial dissection is then begun by carefully bluntly dissecting medial to the adrenal gland, identifying the adrenal vein, and dividing it between clips. Identification of the adrenal vein, particularly on the right side, is easier than with the transabdominal laparoscopic approach. Dissection is completed circumferentially around the gland using electrosurgical or harmonic energy to coagulate any small vessels. Once the gland is completely free, it is placed in a bag and removed through the middle port.

CHAPTER 78 ■ PITUITARY GLAND

WILLIAM F. CHANDLER, ARIEL L. BARKAN, AND RICARDO V. LLOYD

KEY POINTS

- 1 The hypothalamus of the brain is the principal integrating organ for regulating the internal environment of the body, and the pituitary is its major link with the organs outside the nervous system.
- 2 The adenohypophysis constitutes 80% of the gland and contains the pars distalis, pars tuberalis, and remnant of the pars intermedia.
- 3 The neurohypophysis, or posterior pituitary, is small and is virtually an extension of the hypothalamus of the brain.
- 4 Magnetic resonance imaging has evolved as the first choice for diagnostic imaging of the pituitary and is often the only test needed for a therapeutic decision to be made.
- 5 The findings of Cushing syndrome often include central obesity, hypertension, hirsutism, fatigue, easy bruising, striae, moonlike facies, dorsal fat pad, and often depression or other mental changes. The cause of hypercortisolism is an adrenocorticotrophic hormone (ACTH)-secreting pituitary adenoma (Cushing disease) in up to 80% of cases; the remainder are caused by an adrenocortical tumor or an endocrine tumor that secretes ACTH or corticotropin-releasing hormone.
- 6 The three goals of surgery for nonfunctioning macroadenomas are establishment of a diagnosis, decompression of surrounding structures, and gross total removal of tumor tissue, if possible.
- 7 The goals of treatment of adenomas secreting growth hormone are to lower the circulating growth hormone and insulinlike growth factor-1 (IGF-1) levels to a normal range and to reduce the size of the mass lesion that is causing compression-related symptoms.

FIGURE 78.1. Diagram of a 4-week-old embryo illustrating how the Rathke pouch meets the infundibular process to form the anterior and posterior lobes, respectively, of the pituitary gland.

1 The pituitary gland, or hypophysis, is a remarkably complex way station in the connection between the brain and a wide range of organs throughout the body. The hypothalamus of the brain is the principal integrating organ for regulating the internal environment of the body, and the pituitary is its major link with the organs outside the nervous system. The pituitary has been called the “master gland”; even with advances in modern neuroendocrinology, it remains worthy of that description.

EMBRYOLOGY, ANATOMY, AND PHYSIOLOGY

By the fourth week of gestation, an evagination develops in the roof of the stomodeal depression that is lined by ectodermal cells of the cavity destined to become the pharynx (Fig. 78.1). This structure is known as the *Rathke pouch*. At the same time, a depression develops in the floor of the diencephalon; this is called the *infundibular process*. It too is lined with ectodermal cells. These are cells of the future diencephalic portion of the brain and, therefore, are more similar to the cells of central nervous system tissue. During a period of weeks, the two structures grow to meet each other—the infundibular process forming the neurohypophysis (pars neuralis) and the Rathke pouch forming the adenohypophysis (pars distalis). In lower animals, an intermediary lobe (pars intermedia) also forms, but in humans this is present only as a minor cleft. As the adenohypophysis enlarges, its upper portion (pars tuberalis) partially surrounds the stalk connecting the pituitary to the brain. Eventually, the connection between the adenohypophysis and the oral cavity disappears, but occasionally ectopic remnants of nonfunctioning pituitary cells, known as *pharyngeal pituitary tissue*, are left along its path.

2 In an adult, the dimensions of the hypophysis are $6 \times 9 \times 12$ mm, and it weighs about 0.6 g. It enlarges during pregnancy and weighs up to 1 g in multiparous women. The adenohypophysis constitutes 80% of the gland and contains the pars distalis, pars tuberalis, and remnant of the pars intermedia. The pars distalis is the major functional portion of the adenohypophysis, and in this chapter, it is considered synonymous with the adenohypophysis, or anterior pituitary. The neurohypophysis, or posterior pituitary, is small and is virtually an extension of the hypothalamus of the brain.

3 The combined neurohypophysis and adenohypophysis are connected to the base of the brain by a common stalk (Fig. 78.2A). The stalk blends into the median eminence of the hypothalamus and serves to transport both hormone-rich portal blood to the adenohypophysis and nerve fibers to the neurohypophysis. The optic chiasm lies directly above the pituitary, just anterior to the stalk; thus, it is vulnerable to compression by a

pituitary tumor. The supraoptic and paraventricular nuclei of the hypothalamus are depicted in Figure 78.2A because they are the principal locations of cell bodies with axons directed toward the neurohypophysis.

The median eminence is where hormonal contributions from axons originating in various nuclei of the hypothalamus enter blood destined for the adenohypophysis (Fig. 78.2B). Blood reaches this region primarily through the superior hypophyseal artery and flows into gomitoli, which are small capillary plexuses within the median eminence through which hormones enter the blood. The blood then travels through the portal system to the adenohypophysis, where the hormones modulate the activity of secretory cells. These cells, in turn, secrete hormones into the general circulation to stimulate end organs. This system comprises the hormones listed in Table 78.1. Each of these hormonal combinations constitutes a feedback system in which the brain (hypothalamus) senses the level of end-organ hormone output and, in turn, positively or negatively adjusts the secretion of the various hypothalamic hormones into the portal system.

The neurohypophysis differs significantly from the adenohypophysis in that it does not receive controlling hormones by means of the portal system but rather by direct transport through nerve fibers. The principal input into the neurohypophysis is via the supraoptic–hypophyseal tract, which arises from cells within the supraoptic and paraventricular nuclei. The tuberohypophyseal tract, which originates from the central and posterior portions of the hypothalamus, also contributes input to the neurohypophysis. These tracts carry both antidiuretic hormone (ADH; vasopressin) and oxytocin. ADH is secreted into the general circulation and causes the kidneys to reabsorb free water. Elevated levels of ADH (syndrome of inappropriate ADH secretion) cause water retention and hyponatremia, and inadequate levels of ADH (diabetes insipidus) cause dehydration and hypernatremia. Interestingly, surgical loss of the neurohypophysis does not usually result in diabetes insipidus because the stalk itself can still secrete ADH into the circulation. The feedback mechanism to the brain for release of ADH is mainly serum osmolality, with hyperosmolar conditions causing the release of ADH and retention of water. Blood volume also affects the release of ADH; thus, hemorrhage causes water retention. Oxytocin functions only during pregnancy and causes both uterine contractions and milk letdown within the breasts.

The gross surgical anatomy of the pituitary is also critical to the surgeon because the pituitary is closely surrounded by a number of important structures. Figure 78.3A illustrates the coronal cross section of the anatomy of the pituitary as viewed from the front. The pituitary sits within the bony confines of the sella turcica (“Turkish saddle”) and is bordered laterally by the cavernous sinuses (venous), inferiorly and anteriorly by the sphenoid sinus (air), posteriorly by the dorsum sellae, and superiorly by the membranous diaphragma sellae. The cavernous

FIGURE 78.2. A: Schematic diagram of the pituitary and floor of the third ventricle as seen in a midline sagittal view. Anterior is to the left. B: Physiology of hormone release. The adenohypophysis receives releasing hormones through a portal venous system, and the neurohypophysis receives hormones directly from hypothalamic nuclei by means of neurons.

sinuses each contain the siphon region of the internal carotid artery and portions of cranial nerves III, IV, V, and VI, all within a venous plexus. The optic chiasm lies 10 to 15 mm above the diaphragma sellae. Directly below the anterior and inferior portions of the sella is the aerated sphenoid sinus. This is sufficiently large in 97% of patients to allow a transnasal, transsphenoidal surgical approach to the pituitary (Fig. 78.3B).

METHODS OF CELL ANALYSIS

Pituitary adenomas have been classified historically as acidophilic, basophilic, and chromophobic. Adenomas may show a variable staining pattern with conventional hematoxylin and eosin dyes, so it is difficult to classify adenomas based on these stains. For example, prolactinomas and sparsely granulated growth hormone adenomas may be acidophilic or chromophobic after hematoxylin and eosin staining (Table 78.2). Immunohistochemistry, ultrastructural studies, and in situ hybridization analyses for specific hormones are the most reliable methods of classifying pituitary adenomas today.

Other conventional stains that help in the analysis of pituitary adenomas include the reticulin stain, which helps to distinguish between pituitary hyperplasia and adenomas. The normal reticulin pattern is retained in hyperplasia and is similar to normal pituitary tissue, but it becomes disrupted in neoplasia. The periodic acid–Schiff reaction stains carbohydrates in adrenocorticotropic hormone (ACTH)-, thyroid-stimulating hormone (TSH)-, follicle-stimulating hormone (FSH)-, and luteinizing hormone (LH)-producing tumors.

The ultrastructural analysis of pituitary adenomas provides a great deal of information about size and type of secretory granules, cellular synthetic activity, and unique features of specific adenoma subtypes. For example, misplaced exocytosis occurs in prolactin-producing tumors, type I microfilaments are present in ACTH-producing tumors, and abundant mitochondria are characteristic of oncocytic null cell adenomas. The unique honeycomb pattern of the Golgi complex is a distinct morphologic feature of FSH/LH-producing adenomas in women.¹ Because of the pleomorphism and variations in size that are typical of secretory granules, the classification of adenomas is more reliably based on immunohistochemical findings

TABLE 78.1 **DIAGNOSIS****HORMONES INVOLVED IN END-ORGAN STIMULATION**

HORMONE	FUNCTION
Thyrotropin-releasing hormone (TRH)	Stimulates the secretion of thyroid-stimulating hormone (TSH)
Corticotropin-releasing hormone (CRH)	Stimulates the release of adrenocorticotrophic hormone (ACTH)
Growth hormone–releasing hormone (GHRH)	Stimulates the secretion of growth hormone (GH)
Gonadotropin-releasing hormone (GnRH)	Stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
Prolactin-inhibitory factor (dopamine)	Inhibits secretion of prolactin
Somatostatin	Inhibits the secretion of GH and, in part, TSH

bodies against prolactin, growth hormone (GH), ACTH, FSH- β , LH- β , and TSH- β are available for immunohistochemical staining. Many studies with these antibodies have revealed that some pituitary tumors are composed of several cell types that produce various hormones.¹ Ultrastructural immunohistochemistry provides a further degree of refinement in the classification

and study of adenomas, because the exact site of hormone storage in secretory granules and the subcellular sites of production and processing in the rough endoplasmic reticulum and Golgi regions can be visualized with this technique.

Some adenomas may not store specific hormones, so immunohistochemical staining may be weak or absent. Messenger ribonucleic acid (mRNA) is usually present in the cytoplasm of adenomas. The localization of mRNA for specific protein hormones is becoming more widely used in the study and classification of pituitary adenomas. In situ hybridization studies have shown that many GH-producing adenomas in patients with acromegaly also express prolactin mRNA.² Recent studies with microRNAs using polymerase chain reaction methods have demonstrated the importance of specific microRNA in pituitary tumor development.³ In situ and Northern hybridization studies have contributed to the understanding of adenoma subtypes. Null cell adenomas, which constitute up to 15% of pituitary neoplasms, commonly express the mRNA for gonadotropic hormones.

IMAGING OF THE PITUITARY AND PARASELLAR REGION

4 Modern, computerized imaging technology now provides remarkably detailed multiplanar images of the pituitary and parasellar structures. Magnetic resonance imaging (MRI) has evolved as the first choice for diagnostic imaging and is often the only test needed to make a therapeutic decision. With the intravenous infusion of a paramagnetic substance (e.g., gadolinium), MRI demonstrates intrasellar tumors as small as 5 mm and shows the growth pattern of larger tumors. It reveals the extent of suprasellar and sphenoid sinus extension, in addition to lateral extension into the cavernous sinuses (Fig. 78.5).

Cysts and hemorrhages can be differentiated, as can blood flowing within an aneurysm.

Computed tomography (CT) also has a place in pituitary imaging and, if MRI is unavailable, may well suffice as the only mode of imaging. CT shows calcification better than MRI and, thus, is often helpful in imaging a craniopharyngioma. CT, even with intravenous contrast, cannot differentiate an aneurysm, so MRI or angiography must be performed if this is suspected.

Plain skull radiographs are not needed if the diagnosis has been reached by CT or MRI, but they remain a way to identify incidental lesions. A pituitary macroadenoma (>10 mm) causes enlargement of the sella turcica, which can easily be observed on a plain lateral skull radiograph. If this finding is noted on a radiograph performed for any reason (e.g., trauma), a more detailed study (e.g., MRI or CT) should be obtained.

Angiography is performed only if an aneurysm is suspected or if a lesion is so large that occlusion or compression of one or both internal carotid arteries is in question.

CLINICAL AND ENDOCRINE EVALUATION

General Clinical Signs and Symptoms

Patients with pituitary lesions may present with symptoms and signs related to a mass effect on the pituitary and its surrounding structures, hypersecretion of hormones by the lesion itself, or a combination of both. Tumors or other mass lesions are generally larger than 1 cm before they produce symptoms related to compression. As a lesion enlarges, it may cause a loss of pituitary function, usually manifested by a decrease in hormone secretion from the adenohipophysis. This may result in a loss of TSH and subsequent hypothyroidism. A decrease in ACTH results in low serum cortisol levels, and a decrease in

FIGURE 78.5. A: Midpituitary coronal magnetic resonance imaging (MRI) shows a pituitary macroadenoma (M). B: Postoperative MRI demonstrates gross total resection of tumor with cerebrospinal fluid in the sella.

LH and FSH causes amenorrhea in women and hypogonadism in men. A decline in GH is noted only in children with a loss of normal growth progress.

The one exception to this pattern is that generalized pituitary compression may cause a rise in prolactin levels because the secretion of prolactin-inhibitory factor (dopamine) from the hypothalamus or its delivery to the lactotropes may be compromised by the compression. Generalized compression from within the sella rarely results in a loss of ADH from the neurohypophysis and subsequent diabetes insipidus. Lesions that originate in the region of the pituitary stalk, however, often present with early signs of diabetes insipidus. Symptoms related to a loss of pituitary function are usually insidious in onset, except for those of sudden hemorrhage within the sella, or so-called pituitary apoplexy. Such hemorrhages are usually associated with a pituitary adenoma.

When mass lesions in the region of the pituitary enlarge, they may compress or invade nearby structures and cause symptoms unrelated to endocrine function. As tumors or other lesions grow laterally from the sella, they encounter the various contents of the cavernous sinuses. These include the third, fourth, first two divisions of the fifth, and sixth cranial nerves, in addition to the internal carotid artery. Compression of cranial nerves III, IV, or VI causes diplopia, and compression of cranial nerve V causes ipsilateral facial numbness. Invasion or constriction of the carotid artery may cause occlusion of this vessel, which in rare cases results in cerebral infarction. Upward growth of a tumor, which is relatively unrestricted, is much more common and often results in compression of the optic chiasm and loss of vision, typically a bitemporal hemianopsia. Extensive upward intracranial growth may compress the hypothalamus or the third ventricle and cause hydrocephalus. Rarely, intracranial extension results in cortical irritation and associated seizures. Downward growth of tumors into the sphenoid sinus is common but causes no clinical symptoms or signs.

The syndromes associated with hypersecretion of pituitary hormones include Cushing disease (ACTH), acromegaly (GH), hyperprolactinemia (prolactin), and Nelson syndrome (ACTH after adrenalectomy). Rare cases of TSH-secreting adenomas have been documented. Traditionally, pituitary adenomas have been divided into nonfunctioning and functioning tumors, but it has become clear through immunohistochemical studies that many nonfunctioning tumors are in fact endocrinologically active. Although secreted hormones may not cause clinical symptoms or signs, they may serve as a marker for the presence of a tumor before and after treatment.

General Endocrine Evaluation

The extent of the endocrine evaluation of a patient with a pituitary lesion depends on the urgency of the situation (e.g., impaired vision) and whether a hypersecretory state is suspected. If time permits, a careful evaluation of the endocrine status is warranted, including testing of pituitary reserve. Although this is most critical after treatment, it is ideal to obtain a complete pretreatment evaluation for comparison. A pituitary endocrine evaluation should include baseline values for prolactin, GH, insulinlike growth factor-1 (IGF-1), LH, FSH, testosterone, morning cortisol, ACTH, electrolytes, and glucose. Thyroid function tests, including TSH and free thyroxine (T_4), should be performed. Because baseline values may not reflect the ability of the pituitary to respond to stress, it is sometimes necessary to test the reserve capacity of the pituitary. The most efficient way to do this is to administer insulin to induce hypoglycemia. Provided the patient has no contraindication to transient hypoglycemia (i.e., ischemic heart disease, cerebrovascular disease, or seizure disorder), insulin is given in a dose of 0.10 to 0.15 IU/kg, such that the serum glucose falls below 40 mg/dL. In the patient with normal pituitary function, transient hypoglycemia causes a rise in cortisol to above 20 μ g/dL and a rise in GH to above 10 μ g/L. In patients with compromised ACTH or GH production, a response is not noted.

If urgent surgical decompression is indicated, the previously mentioned baseline values are obtained, and the patient is prepared for surgery with sufficient hydrocortisone to cover the possibility of inadequate cortisol response to stress. Careful postoperative evaluation is then carried out to determine if long-term replacement therapy is needed. If the patient receives postoperative radiation therapy, the status of the pituitary should be checked periodically during the following years because pituitary function may slowly decline after radiation exposure.

If diabetes insipidus is suspected, urine and serum osmolality and serum sodium should be assessed, and fluid intake and output should be carefully evaluated.

Cushing Disease

Although the diagnosis of hypercortisolism (Cushing syndrome) is often determined after physical examination by an astute physician, sometimes the physical manifestations are not obvious. Often, the precise cause of hypercortisolism is

5 difficult to ascertain, even with detailed endocrine testing and imaging. The findings of Cushing syndrome often include central obesity, hypertension, hirsutism, fatigue, thin skin, easy bruising, striae, moonlike facies, dorsal fat pad, and depression or other mental changes. Less common abnormalities include headache, osteoporosis, diabetes mellitus, galactorrhea, and amenorrhea. Often, a patient presents without the classic cushingoid appearance and complains only of severe fatigue or depression.

The cause of hypercortisolism is an ACTH-secreting pituitary adenoma (Cushing disease) in up to 80% of cases; the remainder are caused by an adrenocortical tumor or an endocrine tumor that secretes ACTH or corticotropin-releasing hormone. Pituitary-dependent hypercortisolism is much more common in women (80%), and an ectopic cause is more common in men (80%). Thus, if an adult man presents with a rapid onset of Cushing syndrome, particularly with weight loss, hypertension, edema, or hypokalemia, an ectopic neoplasm must be strongly considered. Increased cortisol levels can occur in patients with primary depression, alcoholism, obesity, or drugs such as estrogens and phenytoin.

Because imaging studies are nondiagnostic in up to 60% of patients with pituitary disorders, the diagnosis is often based completely on the results of endocrine testing.⁴ Multiple measurements of cortisol and ACTH to evaluate the diurnal pattern are important but often misleading. They are mainly of value when clearly elevated. Urinary free cortisol excretion over 24 hours is an extremely important measurement, but it may also be elevated in cases of depression or alcoholism. Undetectable plasma or urinary cortisol in a patient with clinically florid Cushing syndrome is unequivocal evidence of exogenous steroid therapy ("iatrogenic Cushing syndrome"). When the result of the overnight dexamethasone screening test (1 mg at 11:00 PM) is an 8:00 AM serum cortisol level below 1.8 $\mu\text{g/dL}$, hypercortisolism is rarely present. The recent development of the salivary cortisol assay permits spot measurement of the free circulating cortisol concentration. Elevated salivary cortisol at 11:00 PM appears to provide strong evidence in favor of endogenous hypercortisolism. The differential diagnosis starts with measurements of plasma cortisol and ACTH: undetectable ACTH in a patient with clinical Cushing syndrome and elevated cortisol establishes the diagnosis of a cortisol-producing adrenal tumor. Plasma ACTH above 200 pg/mL and certainly above 500 pg/mL strongly suggests an ectopic source of ACTH. Most patients with Cushing disease have ACTH within the normal or slightly elevated range. The overlap with the cases of ectopic ACTH secretion, however, is significant and poses the greatest diagnostic difficulty. Generally, the cortisol level of patients with a pituitary cause of hypercortisolism is not suppressed with the low-dose dexamethasone test (0.5 mg given every 6 hours for 2 days), but is with the higher dose (2 mg given every 6 hours for 2 days). The cortisol level of patients with adrenal or ectopic disorders classically is not suppressed with either dose. There are exceptions with both of these tests (Algorithm 78.1).

When metyrapone is given, a rise in serum 11-deoxycortisol (or urinary 17-hydroxycorticosteroids) follows in normal patients or those with Cushing disease, but not in those with adrenal tumors of ectopic ACTH secretion. A positive response, however, does not absolutely rule out an adrenal or ectopic source of hypercortisolism. The most specific differential diagnostic test to distinguish an ectopic ACTH source from Cushing disease is the measurement of ACTH levels in both inferior petrosal sinuses by transfemoral catheterization, along with simultaneous measurement of peripheral blood levels. This should be done prior to and 2 to 10 minutes after an intravenous bolus of corticotropin-releasing hormone. This provides convincing evidence for the existence of an ACTH-secreting pituitary tumor.⁵ Inferior petrosal sinus sampling should be carried out in every case of suspected Cushing disease when MRI results are not *definitive* for a tumor. If the results of standard endocrine testing are conclusive for hyper-

cortisolism and indicate a pituitary source and if MRI clearly shows a tumor, then invasive petrosal sinus sampling is not necessary before surgery.

Nelson Syndrome

In 1958, Nelson et al. identified a syndrome of progressive hyperpigmentation, visual field loss, and amenorrhea associated with elevated ACTH levels related to an ACTH-secreting pituitary adenoma in a patient who had undergone bilateral adrenalectomy for hypercortisolism.⁶ This syndrome today generally represents a missed diagnosis of Cushing disease that has been treated with adrenalectomy. Often these tumors are aggressive or occasionally malignant.

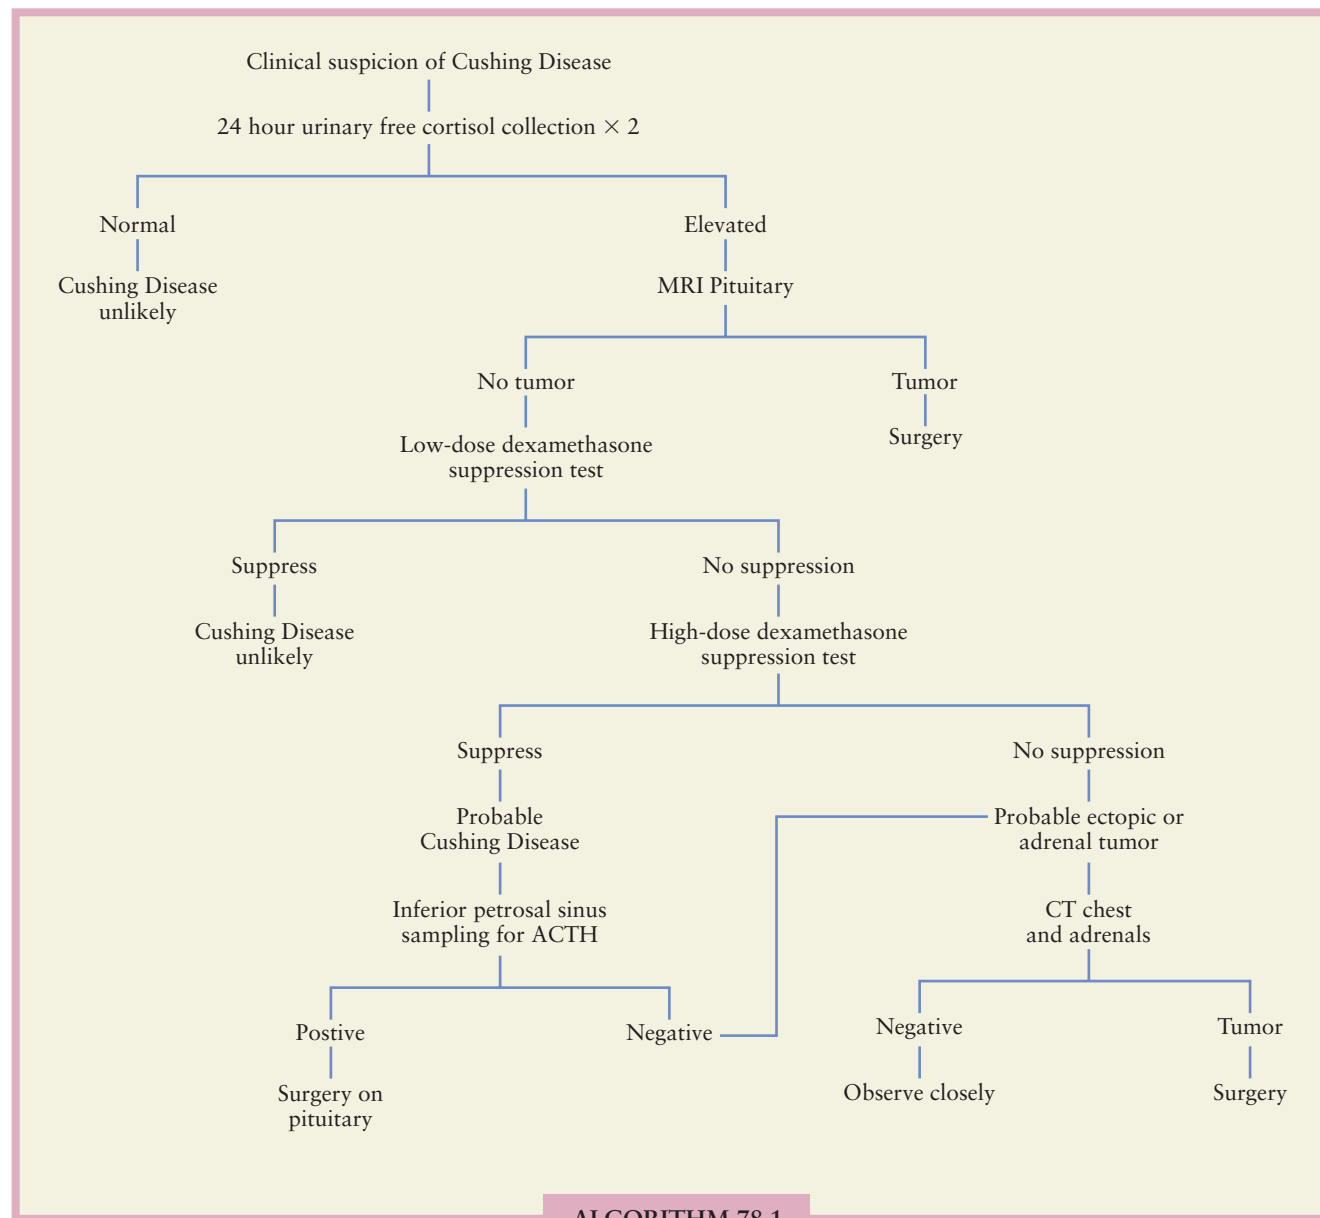

Acromegaly

Like Cushing syndrome, acromegaly can be diagnosed clinically when patients present with advanced stages of the disease. The enlargement of the facial features and extremities may be subtle, and the presenting symptoms may be nonspecific headaches, fatigue, arthralgias, decreased libido, or amenorrhea. Patients often have hypertension, diabetes mellitus, and an early onset of atherosclerotic cardiovascular disease. It is critical that this disease be diagnosed and treated because the associated mortality rate is 50% above normal per decade beyond the age of 40 years. With rare exceptions, the cause of acromegaly is a GH-secreting pituitary adenoma. Like other functioning adenomas, the tumors may be either small or large and invasive. Patients with larger tumors may present with visual loss. Rarely, elevated GH levels are secondary to the production of GH-releasing hormone by an ectopic tumor.

The endocrine diagnosis now rests largely on serum levels of IGF-1, also known as *somatomedin C*. Even though 90% of patients with acromegaly have GH levels higher than 10 ng/mL, and although GH in a resting, nonstressed patient is normally below 5 ng/mL, both normal patients and patients with acromegaly may have levels below 5 ng/mL.⁷ IGF-1, which mediates the effect of GH on peripheral tissues, should be measured in *all* circumstances in which acromegaly is suspected (Algorithm 78.2).

Hyperprolactinemia

Because 60% to 70% of prolactin-secreting pituitary adenomas are microadenomas, most patients present with endocrine symptoms rather than local mass effects. Hyperprolactinemia in women usually causes amenorrhea and often galactorrhea; thus, young women have a reason to seek medical evaluation while the tumor is still at an early stage. Because men do not have these early warning signs, they almost invariably present with macroadenomas associated with loss of libido, infertility, or loss of vision. The finding of amenorrhea or galactorrhea together with an elevated prolactin level does not always indicate the presence of a pituitary tumor. Table 78.3 lists other possible causes of hyperprolactinemia. Most important among these are renal failure, hypothyroidism, and the use of various drugs. Compression of the pituitary stalk by any type of mass lesion results in an increased secretion of prolactin. If the prolactin level is above 200 ng/mL, a pituitary tumor is almost invariably the cause, but microadenomas are often associated with prolactin levels below 100 ng/mL. The size of pituitary adenomas correlates with the degree of prolactin elevation; levels may reach thousands of nanograms per milliliter. No reliable provocative tests are available to differentiate prolactinomas from other causes of hyperprolactinemia, so the diagnosis relies on ruling out other causes and imaging the adenoma (Algorithm 78.3).

ALGORITHM 78.1. Workup and treatment of Cushing disease.

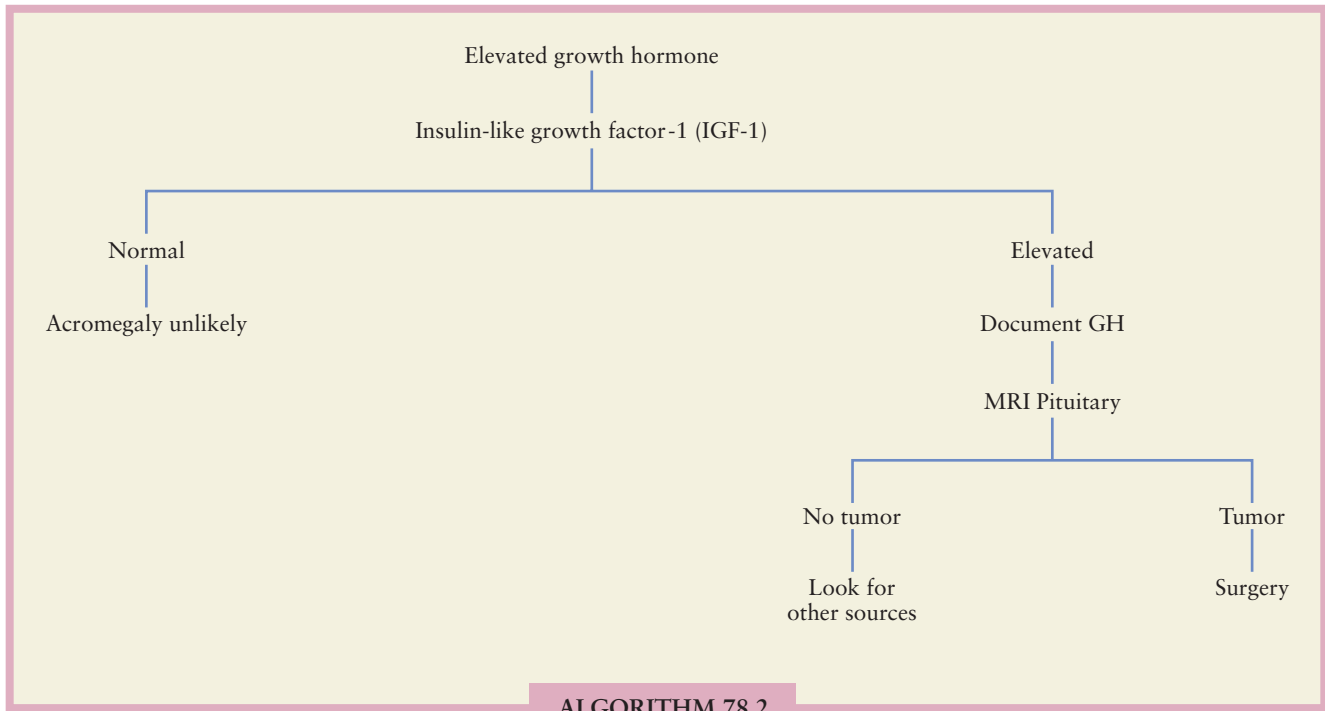

Currently, prolactin is measured by immunoradiometric (IRMA) or immunoluminometric (ILMA) assays, both employing two-site technology. These assays offer rapid and accurate measurement, but suffer from the pitfall of the so-called “hook effect.” At very high prolactin concentrations the assay may report falsely normal or only slightly elevated values. Thus, in any patient having a large pituitary mass (usually >4 cm) that has the potential for being a pituitary adenoma, prolactin needs to be measured in a 1:1,000 diluted sample. Failure to do so may lead to an erroneous diagnosis of a nonfunctioning adenoma and inappropriate surgery instead of medical treatment with a dopamine agonist.

DIFFERENTIAL DIAGNOSIS

Table 78.4 lists the possible lesions that may occur within the sella or in the parasellar region. Pituitary adenomas head the list, because they are the most common lesion in this region and

constitute 8% to 10% of all intracranial tumors. In the report of the Central Brain Tumor Registry of the United States (CBTRUS) for 2000–2004, pituitary tumors are the most common intracranial tumor in the 20- to 34-year age group and the second most common tumor in the 34- to 44-year age group.⁸ They are 30% more common in the black population.

Occasionally, they are cystic and confused with other lesions. Craniopharyngiomas are the next most common tumor, and although more often suprasellar in location, they may be exclusively intrasellar. They are more common in children, but up to one third occur in adults. They are usually cystic and are calcified in 70% of children and 40% of adults. Meningiomas are also more commonly suprasellar and enhance strongly on CT and MRI. Germinomas, or so-called ectopic pinealomas, generally involve the pituitary stalk and often cause diabetes insipidus. If a patient presents with diabetes insipidus, the lesion is likely something other than a pituitary adenoma. Metastatic malignancies, commonly from lung and breast primary tumors, may be found in the pituitary, with

70% residing in the posterior pituitary. Optic nerve gliomas and hypothalamic gliomas may occasionally be confused with pituitary adenomas, as can the rare granular cell tumor (choristoma). Dermoids and epidermoids may occur within the sella, and fifth nerve neuromas may compress the sella.

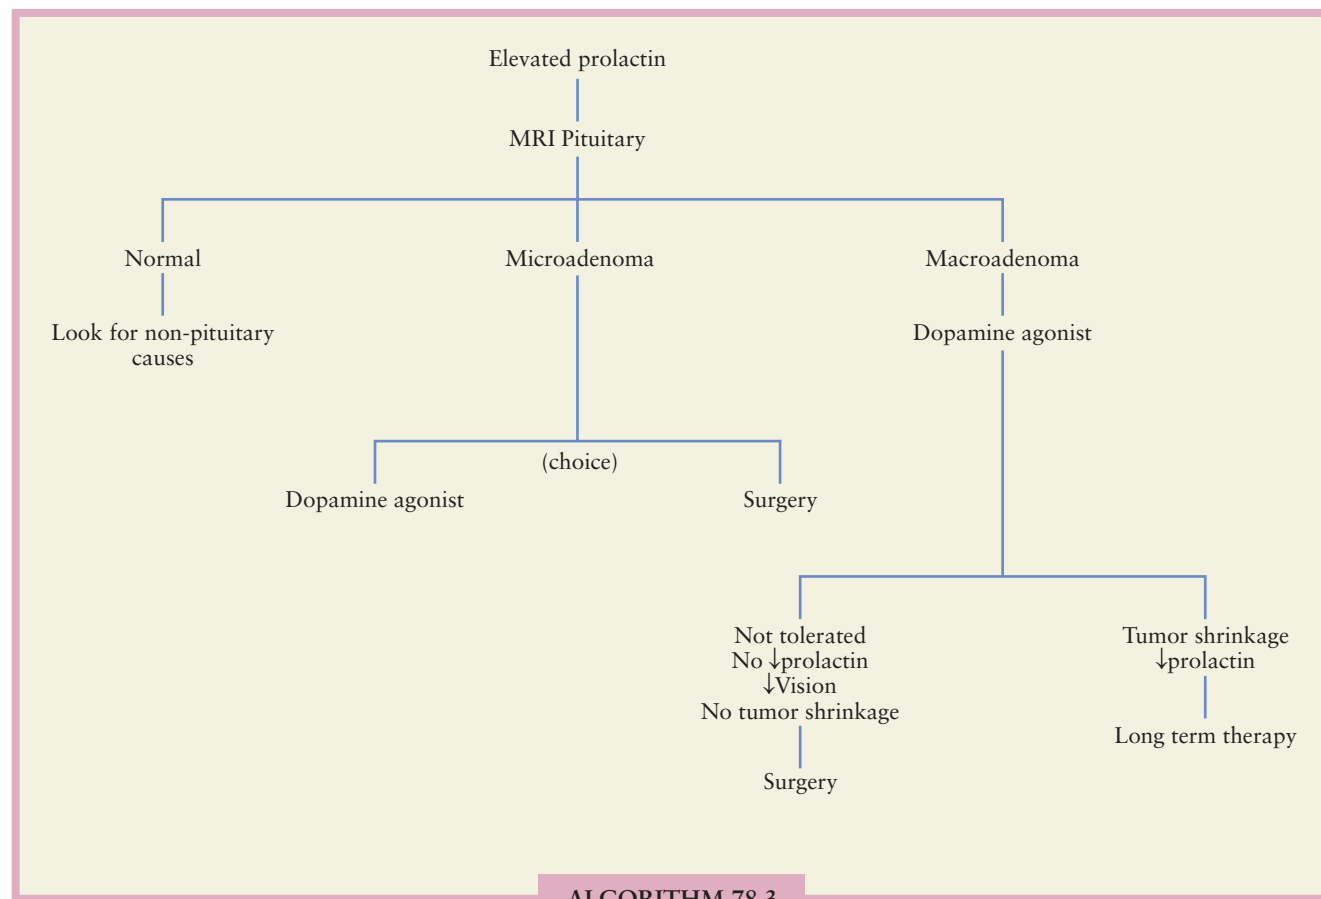

Rathke cysts are benign congenital remnants that develop within the sella and can cause a loss of pituitary function by local compression. These can be confused on imaging studies with cystic adenomas or craniopharyngiomas, and biopsy and surgical decompression is required if the cyst is enlarging or causing symptoms.

Inflammatory and granulomatous processes include bacterial abscesses within the sella and hypophysitis. Sarcoidosis may involve the pituitary or its stalk, as can the granulomas associated with Langerhans granulomatosis (histiocytosis X). Hamartomas may involve the pituitary stalk and hypothalamus and are impossible to differentiate from invasive gliomas on imaging studies.

Aneurysms, usually from the internal carotid arteries but occasionally from the basilar artery, may appear within the sella and must be ruled out preoperatively with MRI or angiography.

The empty-sella syndrome is generally just an anatomic variation that rarely causes symptoms. If a patient with headaches or head trauma undergoes skull radiography or CT, an enlarged sella may be found. With high-resolution MRI, usually the elongated stalk reaches the sellar floor, so that a cystic lesion can be ruled out. A contrast cisternogram may be used to visualize cerebrospinal fluid within the sella if necessary.

Pituitary apoplexy occurs symptomatically only rarely but may cause a profound and emergent situation. Infarction and hemorrhage, usually in a preexisting pituitary adenoma, cause a sudden intrasellar expansion with severe headache and a rapid loss of pituitary function, resulting in hypotension. A sudden loss of vision and other cranial nerve palsies may also develop. Treatment in severe cases involves the administration of steroids and surgical decompression of the sella. Smaller hemorrhages may be managed medically with hormone replacement and serial imaging.

ALGORITHM 78.3

ALGORITHM 78.3. Diagnostic tests and treatment for hyperprolactinemia.

TREATMENT AND RESULTS

The treatment of primary pituitary adenomas is generally surgical, although there are certain exceptions. Even with modern imaging techniques, the unequivocal diagnosis of an adenoma is not reached until tissue is obtained. As shown in Table 78.4, the list of possible parasellar lesions is extensive. Along with surgical removal or decompression of pituitary adenomas, additional treatment in the form of radiation or medical therapy is often indicated. In addition to treatment directed at the primary lesion, it is critical to assess pituitary function thoroughly before and after treatment to decide whether hormone replacement is indicated.

More than 95% of pituitary adenomas can be approached by the transsphenoidal route, usually through a transnasal approach to the sphenoid sinus using the three-dimensional operating microscope. Some pituitary surgeons choose to use the two-dimensional endoscope during part or all of the surgery. Once the sphenoid sinus is entered, the anterior wall of the sella is carefully drilled away, and the dura surrounding the pituitary is identified. The dura is opened, and if a macroadenoma is present, the tumor is usually identified directly beneath the dura. If a microadenoma is present, the surgeon must carefully dissect around and often through the pituitary to identify the small tumor. In selected cases, it is helpful to use a frameless stereotactic system to define the anatomy of the sella and to localize a small tumor. This requires that either preoperative or intraoperative CT or MRI be entered into one of several commercially available frameless stereotactic systems.⁹ This three-dimensional precise localizing system adds to the safety of the transsphenoidal approach and

reduces the chance of injury to surrounding structures, such as the carotid arteries or the cavernous sinuses.

Contraindications to the transsphenoidal approach, and therefore indications for a craniotomy, include massive suprasellar extension, extensive lateral intracranial extension, and the rare dumbbell-shaped tumor with a tight constriction at the level of the diaphragma sellae. If a craniotomy is necessary, a right subfrontal approach to the optic nerve and chiasm is required; the tumor is removed in a piecemeal fashion with use of the operating microscope and microinstruments.

NONFUNCTIONING ADENOMAS

Because patients with nonfunctioning adenomas usually present with the effects of a mass lesion, these tumors are rarely microadenomas. Although their location can be either exclusively intrasellar or extensively suprasellar, almost all of these tumors are currently approached via the transsphenoidal route.

6 The three goals of surgery for nonfunctioning macroadenomas are establishment of a diagnosis, decompression of surrounding structures, and gross total removal of tumor tissue, if possible. The first goal is usually accomplished easily, and although most tumors turn out to be adenomas, surprise findings are not unusual. Decompression is also usually accomplished readily because most tumors are soft and easily removed. Fewer than 5% of adenomas are so fibrous that decompression is difficult. Evidence of adequate decompression is the consistent finding that 75% to 80% of patients with visual field loss show recovery after transsphenoidal tumor removal.¹⁰ The third goal, total tumor resection, is much more

difficult to accomplish with macroadenomas. Most macroadenomas (88% to 94%) invade at least the dura mater, and many grossly invade surrounding structures. Such invasion makes complete surgical resection impossible and, therefore, these patients need to be followed indefinitely with high-quality imaging to monitor tumor progression or recurrence. Whereas it was once common practice to administer postoperative radiation to all macroadenomas, most neurosurgeons are now content to watch for progression with high-resolution imaging and reserve local radiation for progression or recurrence.¹¹ Currently, no medical treatment is available for nonfunctional adenomas.

CUSHING DISEASE

Once it has been established that the cause of a patient's hypercortisolism is a pituitary lesion, the treatment of choice is transsphenoidal exploration of the pituitary. Only 40% of such patients have positive results on imaging studies and, therefore, careful and systematic exploration of the sellar contents by an experienced pituitary surgeon is required in many cases.⁴ Microadenomas secreting ACTH may be very small and are often located deep within the gland itself. If a tumor is not evident when the dura is opened and all surfaces of the pitu-

itary are examined, then incisions must be made into the gland and an internal exploration carried out. These microadenomas are usually located in one of the lateral aspects of the pituitary gland, and the initial choice of which side to explore can be guided by lateralization in the preoperative petrosal sinus sampling for ACTH levels. If no tumor is identified, then a decision must be made regarding whether to resect all or a portion of the gland. If the endocrine evidence is convincing for a pituitary origin and the patient has no desire to have children, then total hypophysectomy is warranted. If petrosal sinus sampling clearly indicates laterality of the ACTH secretion, then an appropriate hemiresection of the gland is carried out. Macroadenomas are treated with maximal tumor resection, but endocrine remission is, of course, more difficult to accomplish in these situations. Obviously, patients with adrenal or ectopic lesions are treated by resection of tumors in these locations. Microadenomas are the source of ACTH secretion in about 75% of patients.^{4,12,13} The postoperative remission rate in these patients is 88% to 96%, and the long-term recurrence rate appears to be no more than 5%. Therefore, selective microsurgical tumor resection in patients with microadenomas is clearly the current treatment of choice. Postoperative plasma cortisol concentrations below 1 $\mu\text{g/dL}$ are a very good predictor of surgical cure, although even in these cases recurrence of Cushing disease occurs in up to 25% of patients within 5 years.¹⁴ If cortisol levels are not in this subnormal range and just in the normal range, a long-term cure is unlikely and the chance of recurrence goes up.

Some 10% to 20% of patients who undergo exploration have macroadenomas, and postoperative remission rates in these patients have been reported to be from 33% to 61%.^{4,12,13,15,16} Most of them require postoperative radiation therapy, which leads to remission in some of the surgical failures. Those whose tumors fail to remit after both surgery and radiation require either a surgical adrenalectomy or medical suppression of adrenal function. In a small percentage of patients who have undergone adrenalectomy, the pituitary tumors continue to grow and secrete ACTH (Nelson syndrome).

ACROMEGALY

Like Cushing disease, acromegaly is a condition that ultimately threatens life. For this reason, it must be treated aggressively, even at the expense of normal pituitary function. During the past two decades, a variety of medical, surgical, and radiation therapies have evolved that have proved effective in lowering GH levels. No single treatment is uniformly effective, and often a combination of treatments is necessary. The goals of treatment are to lower the circulating GH and IGF-1 levels to a normal range and to reduce the size of the mass lesion that is causing compression-related symptoms.

Only 20% to 34% of GH-secreting tumors are microadenomas, however, so that microsurgical tumor resection is less effective than in Cushing disease. When a microadenoma is selectively removed transsphenoidally, endocrine remission may be expected in 80% to 88% of cases. When a macroadenoma is resected, immediate postoperative remission is reported in 30% to 68% of cases.¹⁷ Remission rates are inversely related to preoperative GH levels and the size and invasiveness of tumors.

Radiation therapy has proved moderately effective in conjunction with partial surgical resection. Proton beam heavy-particle therapy was reported in 510 patients, 428 of whom had been observed for 1 to 20 years.¹⁸ Analysis of these patients revealed a progressive fall in GH levels beginning immediately after treatment and continuing for up to 20 years. After 2 years, 47.5% of patients had GH levels below 10 ng/mL; at 4, 10, and 20 years, the rates were 65%, 87.5%, and 97.5%, respectively. A GH level below 5 ng/mL is achieved in

75% of patients at 10 years and 92.5% of patients at 20 years. Conventional radiation therapy provides comparable results (10-year posttreatment levels below 10 ng/mL in 81% and below 5 ng/mL in 69%). A recent review of our own patients, however, showed that after an average follow-up of 6.8 years, normalization of IGF-1 levels was attained in only 2 of 36 patients who received radiation (45 to 50 Gy) after surgical failure.¹⁹ The remaining 34 patients had persistently elevated IGF-1 levels ($219 \pm 26\%$ of upper normal limit) despite plasma GH levels averaging $4.6 \pm 1.1 \mu\text{g/L}$. Normalization of IGF-1 is usually achieved in up to 80% of patients within 5 years after conventional radiation, but the long delay requires medical therapy.²⁰ A report by Landolt et al. suggests that stereotactic radiosurgery may be more effective than fractionated radiotherapy for persistent acromegaly after failed surgical treatment, but there is currently no conclusive evidence that focused radiosurgery is more effective than fractionated radiotherapy.²¹

Bromocriptine, a dopamine-receptor agonist, lowered GH levels in 71% of 126 patients.²² GH levels below 10 ng/mL, however, were achieved in only 14% of patients in this study. Bromocriptine does not appear to be an effective primary treatment for acromegaly, but may help to control GH and IGF-1 levels as an adjuvant therapy. Cabergoline offers an advantage of longer action and lower incidence of side effects, but only rarely normalizes IGF-1 on its own.

Somatostatin analogues, octreotide (Sandostatin LAR), and lanreotide (Somatuline Depot) have been demonstrated to reduce GH and IGF-1 levels significantly in most patients and may provide tumor shrinkage, but GH levels rise again after cessation of the drug. A GH-receptor blocker, pegvisomant, has proved useful in lowering IGF-1 levels in patients whose disease cannot be controlled by surgery or somatostatin analogues. Because this drug works peripherally, there is still concern that the pituitary tumor may grow and enlarge during this treatment, although recent data suggest that this may not be the case.

Given the variety of treatment modalities, a rational therapeutic approach is to resect tumors surgically when possible and to provide medical and radiation therapy to those patients in whom a remission cannot be achieved. The recurrence rate of GH-secreting tumors appears to be only 4% after successful surgery and less than 1% after radiation.²¹

PROLACTINOMAS

Prolactin-secreting adenomas are the most common functioning pituitary tumors but remain somewhat controversial with regard to treatment. The controversy exists because, unlike ACTH- or GH-secreting adenomas, prolactinomas can be treated medically with dopamine agonists, with excellent results. The treatment options include medical therapy, usually with a dopamine agonist; transsphenoidal surgical resection; radiation therapy; or, in some cases, no treatment. Because treatment considerations depend on tumor size, the treatments are discussed on that basis.

Macroadenomas

The goal in treating a patient with a large, prolactin-secreting adenoma is to decompress the optic pathways if they are involved and to reduce the prolactin levels to normal concentrations. Surgery is effective in improving vision in 80% of cases, but vision also usually improves in patients treated with dopamine agonists. The success of surgery in reducing prolactin levels to normal has generally been disappointing. The uniform finding of various investigators has been that the likelihood of surgical normalization of prolactin levels is greatly

reduced if the initial concentration is above 200 ng/mL or if the macroadenoma is larger than 10 mm.

The administration of dopamine agonists to patients with macroadenomas reduces prolactin levels significantly in almost all instances, and reductions to normal ranges have been reported in more than 46%.²³ In 90% of patients, the size of the tumor is decreased to some degree and, in many, the reduction is dramatic. With rare exceptions, however, the tumor returns to its original size once bromocriptine or cabergoline is stopped. It is recognized that up to 25% of patients with macroadenomas experience an increase in tumor size during pregnancy, whereas this is true in fewer than 1% of patients with microadenomas.²³

In most instances patients with macroprolactinomas are treated initially with a dopamine agonist and surgery is reserved for the rare situation in which the patient is not responsive to this medication. Occasionally, patients with prolactinomas present with significant hemorrhage within the tumor and require surgical debulking of the hemorrhage and surrounding tumor.

Microadenomas

Primary medical treatment with a dopamine agonist is safe and effective and is currently the treatment of choice for most patients with a prolactin-secreting microadenoma. As in macroadenomas, long-term continued therapy is indicated because prolactin levels rapidly rise with cessation of dopamine agonists in most patients. Pregnancy is of less risk to the patient with a microadenoma because tumor expansion and visual loss are rare.

The surgical treatment of prolactin-secreting microadenomas results in postoperative remission in a much higher percentage of patients. Two large series reported remission in 77%²⁴ and 72%²⁵ of patients. In the latter report, 88% of patients with preoperative prolactin levels below 100 ng/mL were in remission, as opposed to only 50% in those who had preoperative prolactin levels above 100 ng/mL. The incidence of new postoperative hypogonadism was only 1%. The recurrence rate in patients initially in remission after microsurgical tumor removal, however, has been disappointing compared with the rates after removal of other functioning tumors. Recurrences have uniformly been found to be higher in patients with postoperative prolactin levels in the upper end of the normal range. Recurrence rates of 17% to 50% during 5 years have been reported. Radiation therapy does not play a role in the treatment of microadenomas unless they recur in an aggressive manner.

CHAPTER 79 ■ LUNG NEOPLASMS

ANDREW C. CHANG AND JULES LIN

KEY POINTS

- 1 Lung cancer remains the leading cause of cancer-related death in the United States.
- 2 Resection remains the mainstay in the treatment of lung cancer, yet only about 20% of all patients diagnosed with lung cancer are considered resectable (stages I to IIIA). Video-assisted thoracoscopic surgery/robotic approaches have changed the landscape for operation, although the principles of oncologic resection remain unchanged.
- 3 Advances in molecular biology including genomic and proteomic techniques constitute promising methodologies for the diagnosis and patient-tailored management of non-small cell lung cancer (NSCLC), but to date these strategies have not been validated for broad clinical implementation.
- 4 Updated staging criteria for NSCLC are available that stratify patient survival based on outcomes data collected worldwide.
- 5 Common sites of distant metastases are bone, liver, bone marrow, and the central nervous system; therefore, the metastatic evaluation includes a bone scan and computed tomogram of the chest, abdomen, and brain.
- 6 Taken as a whole, neoadjuvant therapy trials have demonstrated the feasibility of induction chemotherapy and radiation followed by resection for the treatment of selected stage IIIA NSCLC. Most studies show improved rates of resectability and survival in comparison with the historical experience for surgical resection or radiation alone.
- 7 In addition to new chemotherapeutic agents, new radiation techniques, such as hyperfractionated or accelerated schedules, also merit further exploration in neoadjuvant trials with concurrent chemotherapy.
- 8 Generally, a solitary lesion is more likely to be a metastasis if the primary tumor was a sarcoma or a melanoma. If the primary tumor originated in the head, neck, or breast, it is more likely to be a new primary lung cancer.

Although population estimates of both the incidence and mortality of lung cancer have begun to decline, lung cancer was second only to heart disease among all causes of mortality reported for 2005. Lung cancer is second in cancer prevalence only to prostate cancer among men and breast cancer among women. With 215,020 new cases and 161,840 deaths projected for 2008, lung cancer remains the leading cause of cancer-related death in both sexes in the United States. Although annual mortality rates due to lung cancer are decreasing among men, lung cancer-related deaths among women continued to increase by 0.2% per year from 1995 to 2004.¹ There is also significant regional variation in both lung cancer incidence and mortality. Among men, lung cancer mortality has decreased from 1996 through 2005 in over 80% of the 50 states and the District of Columbia, whereas among women over the same period, mortality decreased in only three states (California, New Jersey, and Texas) and has increased in 13 other states, primarily in the Midwest and South.²

- 2 The best predictor of survival for patients with lung cancer is still tumor stage. Resection remains the mainstay in the treatment of lung cancer, yet only approximately 20% of all patients diagnosed with lung cancer are considered resectable (stages I to IIIA). Even among patients who have undergone complete curative resection for early-stage disease, as determined using pathologic tumor–node–metastasis (TNM) criteria, a substantial number will have recurrence of their cancer.³

Clinical trials continue to demonstrate that adjuvant chemotherapy can improve survival over surgery alone for early-stage lung cancer,^{4–6} but it remains to be seen whether earlier tumor detection by modalities such as screening chest computed tomography (CT) will impact overall survival.^{7,8} In addition, as understanding of the molecular changes occurring in lung cancer evolves, new strategies that allow for early detection and classification of lung cancer will provide valuable information for the treatment of patients.

HISTORY

Ferdinand Sauerbruch, whose interests included the physiology of pneumothorax and who is considered one of the pioneers of thoracic surgery, reported the first successful lobectomy for lung carcinoma in 1920. At that time, it was believed that only total pneumonectomy would provide a cure for lung cancer. Although this was neither the first pulmonary resection nor pneumonectomy, Dr. Evarts A. Graham performed the first successful single-stage pneumonectomy for a left upper lobe bronchogenic carcinoma in 1933,⁹ establishing the modern era of thoracic surgery for lung cancer. Ultimately, Dr. Graham succumbed to lung cancer in 1957 and was outlived by his patient, Dr. James L. Gilmore, who had continued to smoke.¹⁰

EPIDEMIOLOGY

Recently, population studies have demonstrated a continued decline in lung cancer incidence among men (83.5 cases per 100,000) and stabilization of disease incidence among women (49.2 per 100,000) as of 2001. African American men continue to have the greatest incidence of lung cancer, in excess of nearly 50% (124.5 per 100,000) over the cases reported for all men.¹¹ The decline in incidence as well as mortality may be due in part to public health efforts to promote smoking cessation.¹² In a follow-up to the Seven Countries Study of smoking-related mortality, follow-up analysis of the initial cohorts studied from Europe, the United States, and Japan confirmed that cigarette smoking increased the risk for death due to lung cancer with a hazard ratio of 4.2 per pack of cigarettes smoked. Furthermore, the death rates due to lung cancer decreased to that of never-smokers after 10 years of smoking cessation.¹³ Exposure to environmental “second-hand” cigarette smoke can also contribute to an increased risk of lung

cancer.¹⁴ The European Prospective Investigation into Cancer and Nutrition (EPIC), a recent nested case-control study of a cohort of 123,479 EPIC enrollees, demonstrated that former smokers and subjects with environmental smoke exposure were at greater risk for developing lung cancer over a median follow-up period of 7 years.¹⁵

PATHOLOGIC CLASSIFICATION

Uniform classification of lung cancer is important both to provide consistent treatment for patients and to allow standardization in reports of epidemiologic, clinical, and basic scientific studies. Currently, the classification is largely histologic and is based on light microscopy findings determined from specimens obtained by resection or needle biopsy, permitting its wide application by surgical pathology laboratories where more advanced techniques might not be readily available. Nevertheless, immunohistochemical and electron microscopy analyses are important, particularly in the diagnosis of neuroendocrine tumors or in distinguishing between primary bronchogenic adenocarcinoma and metastatic lesions. The most recent revision of the World Health Organization (WHO) classification (Table 79.1) was published in 2004¹⁶ but is largely unchanged from the previous revision in 1999.¹⁷ Guidelines for defining preinvasive lesions such as squamous dysplasia and carcinoma in situ are provided. Recognition and definition of the heterogeneity among adenocarcinomas is reflected in the subclassification of this group, including more restrictive definitions for bronchioloalveolar carcinoma (BAC). Definitions for the spectrum of neuroendocrine tumors, ranging from typical and atypical carcinoid to small cell lung cancer (SCLC) and large cell neuroendocrine carcinomas, are provided.

TUMOR BIOLOGY

Genetic alterations in several regulatory pathways including apoptosis, the cell cycle, and mitogenic signaling have been identified in tumors of patients with non-small cell lung cancer (NSCLC). Chromosomal loss of heterozygosity (LOH) or allelic gain appears to occur more frequently among patients with adenocarcinoma and history of tobacco exposure than among patients without any smoking history. Mutations among the Ras oncogenes, particularly K-ras, are characterized by the accumulation of DNA adducts within these genes, predominantly among patients with a history of tobacco use.¹⁸ This has been attributed to the exposure to tobacco carcinogens such as benzo[a] pyrene (BaP); its activated form, benzo[a]pyrene diol epoxide (BPDE); and N-nitrosamines. These genes encode guanosine triphosphate (GTP)-binding proteins that participate in cellular signal transduction; their mutation results in constant Ras activation. Another family of oncogenes, Myc, encoding several transcription factors, is activated by gene amplification, primarily in SCLC.¹⁸

The tumor-suppressor gene p53 is the most frequently mutated gene in human cancer. Among patients with a history of tobacco use, mutations within p53 were identified in over 50% of patients with NSCLC, particularly squamous cell carcinoma (SCC) and non-BAC adenocarcinoma.^{19,20} Among patients with stage I tumors, those with mutations, particularly truncating, structural, or those that abolished DNA contact, demonstrated significantly worse actuarial survival in comparison with patients who had wild-type p53. In contrast, those patients with missense mutations did not demonstrate significantly different survival than those with wild-type p53. In patients with more-advanced-stage tumors, mutations in p53 did not identify patients at risk for worse outcomes, suggesting that the effects of p53 mutation may be diluted by the

accumulation of mutations at loci important in the later stages of tumorigenesis.¹⁹ Interestingly, investigators have also identified p53 protein expression, determined by immunohistochemical analysis, as a predictor of poor outcome in patients with stage I NSCLC.²¹ Furthermore, p53 expression is also associated with tumors more likely to demonstrate distant metastases.²² Although mutational analyses were not reported in these immunohistochemical studies, these findings may be concordant, since it is possible that p53 mutations may result in greater steady-state levels of p53 protein, allowing for increased detection by immunohistochemistry.²³

Epigenetic mechanisms of gene regulation also appear to participate in tumorigenesis of lung cancer. In particular, gene promoter inactivation by hypermethylation may be an important mechanism in the inactivation of tumor-suppressor genes such as p16^{INK4a} (p16), an inhibitory regulator in the cyclin D–retinoblastoma cell cycle pathway. In patients with premalignant lesions such as squamous dysplasia and carcinoma in situ, both allelic loss and hypermethylation of p16 have been identified, with associated decreases in p16 protein expression,²⁴

suggesting that loss of p16 may be an important early event in NSCLC tumorigenesis.²⁵

3 Investigators have attempted to identify genome-wide molecular events occurring in lung cancer and to relate these changes to tumor classification, patient prognosis, or even response to therapy. Microarray analyses, encompassing a multitude of methodologic approaches, have the potential to provide the investigator with an abundance of data describing changes in gene or protein expression.²⁶ Several groups have demonstrated that large-scale gene expression studies can identify patterns of expression distinguishing squamous cell carcinoma, adenocarcinoma, and small cell lung cancer.^{27,28} Furthermore, within groups of patients with bronchogenic adenocarcinoma, tumor heterogeneity can be identified, distinguishing not only tumor grade and differentiation but also patient outcomes.²⁸⁻³¹ These studies, although largely retrospective, demonstrate the potential for gene and protein expression “profiles” to be utilized as diagnostic and prognostic tools in the treatment of lung cancer. Before these techniques can be broadly applied, even in prospective clinical trials, issues of reproducibility between institutions and across analytic platforms must be addressed.³² Distinguishing those genes that appear to be involved causally in lung cancer tumorigenesis from those genes that are regulated secondarily is critical for our understanding of this disease and for the identification of potential targets for therapeutic intervention.

Historically, clinical trials demonstrated that only 10% to 19% of patients with chemotherapy-refractory advanced NSCLC responded to treatment with the tyrosine kinase inhibitor gefitinib. Furthermore, the addition of gefitinib to standard chemotherapy yielded no demonstrable benefit.³³ As proof of concept for targeted molecular therapy, two groups demonstrated that tumors obtained from patients who exhibited rapid and dramatic tumor response to gefitinib were more likely to have mutations in the epidermal growth factor receptor (EGFR).^{33,34} In contrast, gefitinib-insensitive tumors did not contain similar mutations. Supporting this finding, retrospective analyses of patients with NSCLC indicated that patients with adenocarcinoma of bronchioloalveolar subtype and “never-smokers,” defined as patients with a less than 100-cigarette lifetime smoking history, were more likely to respond to treatment with gefitinib,³⁵ and mutational analysis of these gefitinib-sensitive tumors contained similar somatic mutations.³⁶ These data represent an exciting potential application of gene expression studies for use in determining patient prognosis and in the clinical management of lung cancer in preventing over- or undertreatment of patients.

NON-SMALL CELL LUNG CANCER

4 The diagnosis of lung cancer should be directed by the presumed stage of disease at patient presentation. Accurate and reproducible TNM staging of lung cancer allows clinicians to provide consistent treatment of lung cancer and provides the basis for uniform reporting of clinical research across institutions and study groups. In 1997, revisions in the International System for Staging Lung Cancer (Table 79.2) were adopted by the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC), based on 5,319 cases of lung cancer.³ Changes for the seventh edition of the TNM classification of malignant tumours for NSCLC staging³⁷ were proposed by the International Association for the Study of Lung Cancer (IASLC). The revisions arise from evaluation of 67,725 cases of NSCLC with broad geographic diversity including subjects from Asia, Australia, Europe, and North America.^{37,38} The revisions address both T³⁹ and M⁴⁰ designations (Table 79.3), with no changes suggested for the current nodal classification schema (Table 79.4).⁴¹ Stratification of patient

survival, particularly among subjects with pathologic stage IB and IIA cancers, was more distinct with application of the seventh edition criteria (Table 79.5).

Guidelines for surveillance of the incidentally detected sub-centimeter nodule (<8 to 10 mm) or larger solitary pulmonary nodule (8 to 10 mm or larger) have been published by the Fleischner Society for Thoracic Imaging and Diagnosis,⁴² the American College of Chest Physicians,⁴³ and others⁴⁴ and are incorporated in a suggested algorithm (Algorithm 79.1) for evaluation of these common incidental chest findings. As with any algorithm, assessment of patient risk factors (pretest probability) for cancer⁴³ as well as comorbidities⁴² should be taken into consideration before following these guidelines in one's practice.

The aims of the initial evaluation of a patient with NSCLC are to determine whether distant metastatic disease is present and to assess the extent of intrathoracic disease. A multidisciplinary approach, involving input from pulmonary medicine, chest radiology, oncology, and thoracic surgery, should be undertaken in the selection of the most suitable testing for any individual patient. One general algorithm for patient evaluation and decision making is shown in Algorithm 79.2. A thorough history and physical examination, combined with a plain chest radiograph and baseline laboratory data (complete blood cell count and measurement of serum sodium, calcium, alkaline phosphatase, and lactate dehydrogenase levels), can suggest the presence of metastatic disease. Common metastatic sites include the brain, supraclavicular nodes, contralateral lung, bones, liver, and adrenal glands. Abnormal findings are then investigated further with chest CT and fluorodeoxyglucose positron emission tomography (FDG-PET) body scans. If necessary, needle aspiration biopsy or open biopsy can be performed to determine the extent of disease.

If the initial clinical evaluation does not suggest the presence of distant disease, the extent of further evaluation by various scans is controversial. Some physicians always perform a complete metastatic workup with CT of the chest and abdomen, CT or magnetic resonance imaging (MRI) of the brain, and FDG-PET scan. CT of the chest and upper abdomen has become standard, as much to evaluate the extent of the primary tumor and the status of the mediastinal lymph nodes as to detect metastases in the ipsilateral or contralateral lung, liver, or adrenals. Additional scans in asymptomatic patients may detect the 5% to 10% of metastases that are occult, but these scans are not clearly cost-effective in patients with clinical stage I or II tumors.

Patients presenting with suspected NSCLC and a pleural effusion should undergo thoracentesis, followed by thoracoscopy should initial cytology specimens be nondiagnostic. Those patients presenting with metastatic (stage IV) disease involving a solitary distant site should obtain tissue confirmation at the site of metastasis, if technically feasible. If noninvasive testing demonstrates multiple metastases (e.g., multiple liver, brain, or bone lesions), then diagnosis of the primary lesion might provide the most efficient means of diagnosis, followed by the initiation of palliative chemotherapy.⁴⁵ In patients who are suitable candidates for operation, who have a suspicious solitary pulmonary nodule that is of indeterminate origin despite appropriate evaluation, excisional biopsy and subsequent lobectomy of resectable lung cancer should be pursued.⁴⁶

Recent multi-institutional studies have indicated a benefit for a combined modality approach in the treatment of stage IIIA NSCLC, consisting of neoadjuvant chemotherapy and radiation followed by resection (Intergroup0139/RTOG9309). Therefore, tissue confirmation of mediastinal nodal involvement has implications not only for the staging but also the management of patients who are otherwise candidates for resection of locoregionally advanced NSCLC. Regional lymph node involvement (N) has been defined as follows: N0 = no lymph node metastasis; N1 = metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region or both, including direct extension;

TABLE 79.2

CLASSIFICATION

TNM CLASSIFICATION FOR STAGING SYSTEM OF NON-SMALL CELL LUNG CANCER (6TH EDITION)

■ STAGE		■ TNM STATUS
IA		T1 N0 M0
IB		T2 N0 M0
IIA		T1 N1 M0
IIB		T2 N1 M0
		T3 N0 M0
IIIA		T3 N1 M0
		T1–3 N2 M0
IIIB		T4 Any N M0
		Any T N3 M0
IV		Any T any N M1
TNM DEFINITIONS		
T	TX	Positive malignant cells, but primary tumor not visualized by imaging or bronchoscopy
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor ≤3 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus ^a
	T2	Tumor with any of the following features of size or extent: >3 cm in greatest dimension Involves main bronchus, ≥2 cm distal to the carina Invades the visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
	T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, or parietal pericardium; tumor in the main bronchus <2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
	T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; or tumor with a malignant pleural or pericardial effusion, or with satellite tumor nodule(s) within the ipsilateral primary tumor lobe of the lung ^b
N	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and involvement of intrapulmonary nodes by direct extension of the primary tumor
	N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
	N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M	MX	Presence of distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis present (including metastatic tumor nodule[s] in the ipsilateral nonprimary tumor lobe of the lung)
^a The uncommon superficial tumor of any size with its invasive component limited to the bronchial wall that may extend proximal to the main bronchus is classified as T1.		
^b Most pleural effusions associated with lung cancer are caused by tumor. There are, however, some few patients in whom the pleural fluid (more than one specimen) is negative for tumor on cytopathologic examination and in whom the fluid is nonbloody and is not an exudate. In cases in which these elements and clinical judgment dictate that the effusion is not related to the tumor, the patient should be staged T1, T2, or T3, with effusion excluded as a staging element. Pericardial effusion is classified according to the same rules.		

N2 = metastasis to ipsilateral mediastinal lymph nodes and subcarinal lymph nodes; and N3 = metastasis to contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, and ipsilateral or contralateral scalene or supraclavicular lymph nodes (Table 79.4).⁴⁷

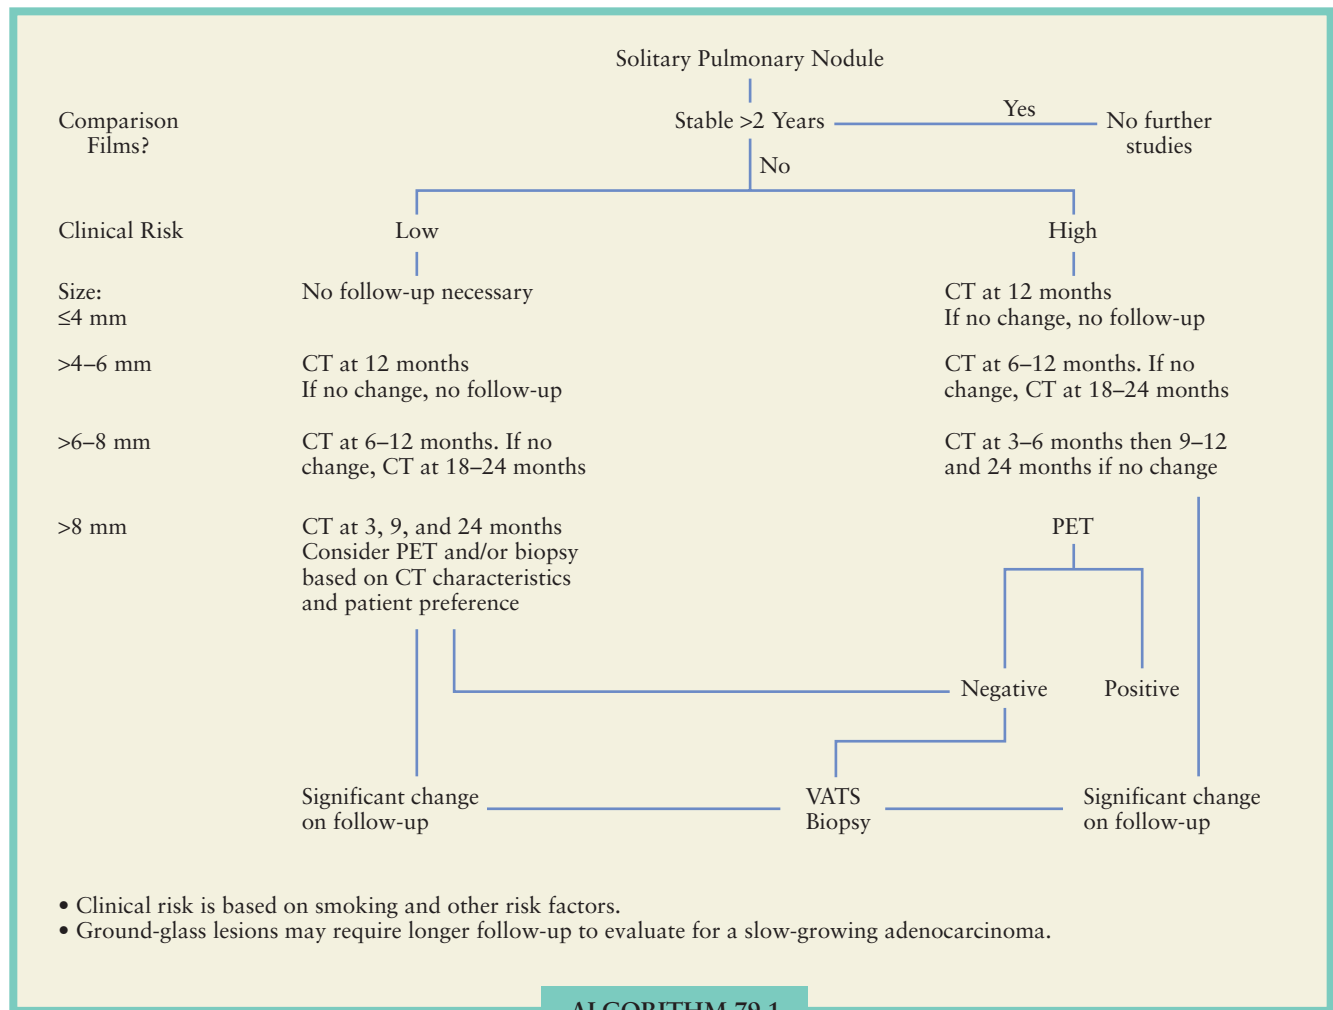

Chest CT provides only anatomic clues for tumor involvement of mediastinal lymph nodes (enlargement >10 mm), as demonstrated in a recent meta-analysis of over 3,400 evaluable

patients, with a pooled sensitivity of 57% and specificity of only 82%. This meta-analysis also demonstrated that FDG-PET scanning appears to provide increased sensitivity of 84% and specificity of 89% in over 1,100 patients studied for the detection of mediastinal malignancy.⁴⁸ Several single-institution prospective studies have also indicated the superior diagnostic accuracy of FDG-PET imaging.^{49–51} A recent multi-institutional trial involving 271 patients confirmed these findings. Although

ALGORITHM 79.1. Management of the incidental solitary pulmonary nodule. (Partially based on MacMahon H, Austin JHM, Gamsu G, et al. Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society. *Radiology* 2005;237:395–400.)

TABLE 79.4

CLASSIFICATION

THE MOUNTAIN-DRESLER LYMPH NODE MAP

■ NODAL STATION	■ ANATOMIC LANDMARKS
N2 nodes: All N2 nodes lie within the mediastinal pleural envelope	
1. Highest mediastinal nodes	Nodes lying above a horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline
2. Upper paratracheal nodes	Nodes lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of No. 1 nodes
3. Prevascular and retrotracheal nodes	Prevascular and retrotracheal nodes may be designated 3A (anterior to the vessels) and 3P (prevertebral); midline nodes are considered to be ipsilateral.
4. Lower paratracheal nodes	The lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope; the lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin to the aortic arch and a line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the mediastinal pleural envelope. Researchers may want to designate the lower paratracheal nodes as No. 4s (superior) and No. 4i (inferior) subsets for study purposes; the No. 4s nodes may be defined by a horizontal line extending across the trachea and drawn tangential to the cephalic border of the azygos vein; the No. 4i nodes may be defined by the lower boundary of No. 4s and the lower boundary of No. 4 as described above.
5. Subaortic (aortopulmonary window)	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope.
6. Para-aortic nodes (ascending aorta or phrenic)	Nodes lying anterior and lateral to the ascending aorta and the aortic arch or the innominate artery, beneath a line tangential to the upper margin of the aortic arch
7. Subcarinal nodes	Nodes lying caudal to the carina of the trachea but not associated with the lower lobe bronchi or arteries within the lung
8. Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes
9. Pulmonary ligament nodes	Nodes lying within the pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein
N1 nodes: All N1 nodes lie distal to the mediastinal pleural reflection and within the visceral pleura	
10. Hilar nodes	The proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiographically, the hilar shadow may be created by enlargement of both hilar and interlobar nodes.
11. Interlobar nodes	Nodes lying between the lobar bronchi
12. Lobar nodes	Nodes adjacent to the distal bronchi
13. Segmental nodes	Nodes adjacent to the segmental bronchi
14. Subsegmental nodes	Nodes around the subsegmental bronchi
Definition of the anatomic boundaries for each lymph node region facilitates correlation between findings at operation and findings on chest computed tomography. After Mountain CF, Dresler CM. Regional lymph node classification for lung cancer staging. <i>Chest</i> 1997;111:1718.	

the overall sensitivity and specificity of FDG-PET staging was 61% and 84%, respectively, there was a significant improvement with FDG-PET over chest CT in the detection of both hilar (N1) lymph node (42% vs. 13%, $p = 0.0177$) and mediastinal (N2 and N3) tumor involvement (58% vs. 32%, $p = 0.004$). Whereas FDG-PET scanning can increase the suspicion of malignancy, its negative predictive value for mediastinal lymph node involvement does not appear to be sufficient, with a false-negative rate reported as high as 13%.⁵² PET evaluation of the solitary pulmonary nodule also appears to be somewhat insensitive, with a negative predictive value for benign lesions of only 57%, indicating a false-negative rate of 47%. Reliance on this modality could lead to delayed treatment for resectable early-stage (IA) NSCLC.⁵³ Integrated CT-PET imaging, in

which concurrently performed chest CT provides anatomic correlation for positive PET findings, appears to provide more precise staging, particularly regarding tumor and nodal status,⁵⁴ and also can be used to guide further invasive testing in the accurate staging of lung cancer.

Ultimately, tissue confirmation of noninvasive findings must be obtained, particularly in the setting of large, prospective trials being undertaken to determine the efficacy of neoadjuvant and adjuvant therapy.⁵⁵ Noninvasive techniques for clinical staging, particularly chest CT, have a reported false-negative rate of approximately 10% to 15%. FDG-PET scan also has a reported false-positive rate of as high as 50%.⁴⁹ Clinical staging of NSCLC, particularly mediastinal lymph node involvement, can be accomplished by needle aspiration

ALGORITHM 79.2. Evaluation of the patient who presents with a pulmonary mass.

techniques from several approaches: transbronchial (TBNA) with or without endobronchial ultrasound (EBUS) guidance, transthoracic, or transesophageal. Transesophageal endoscopic ultrasound with fine-needle aspiration (EUS-FNA) appears to be particularly useful for sampling of posterior mediastinal nodes such as the subcarinal, periesophageal, or aortopulmonary window stations, particularly in patients with mediastinal lymphadenopathy in these regions. Diagnostic yield is improved with practitioner experience, sampling needle size, and on-site cytology examination to determine adequacy of the obtained samples.

Cervical mediastinoscopy remains the “gold standard” for tissue diagnosis of mediastinal lymphadenopathy, with procedural sensitivity greater than 90% and specificity of 100%.⁵⁶ A recent retrospective review of a single institutional experience with routine mediastinoscopy, including 1,745 patients with known or suspected lung cancer, demonstrated overall sensitivity of 85%, with most false-negative results due to lymph node involvement in regions inaccessible to standard mediastinoscopic technique; morbidity of 0.6%; and perioperative mortality of 0.05%. Furthermore, of the patients found to have N2 or N3 disease at mediastinoscopy, only 6.6% (28/422) subsequently underwent resection, including several patients treated on neoadjuvant protocol.⁵⁷ For patients with clinically suspicious aortopulmonary lymph node involvement (stations 5 and 6), an area that is generally not accessible by standard mediastinoscopy, anterior mediastinotomy, extended cervical mediastinoscopy, or, as of more recently, thoracoscopy can be performed.

One recent goal in the diagnosis of lung cancer has been the early detection of tumors arising in asymptomatic high-

prevalence populations (e.g., older patients with a history of tobacco use). Whether such efforts actually alter the natural history of disease remains controversial.^{7,8,58,59} While newer modalities of noninvasive imaging, such as FDG-PET imaging, have improved the accuracy of staging for lung cancer,⁵² these techniques still rely on factors such as tumor cell volume, tumor density, and metabolic activity. Current staging procedures do not detect all lymph node or distant hematogenous metastases.

Risk Assessment

Having established that resection is feasible, a significant number of patients with lung cancer cannot undergo operation due to associated comorbidity that increases operative mortality and postoperative morbidity. Age alone should not preclude patients with resectable disease from operation.⁶⁰ In a population with a high prevalence of prior or continuing tobacco use that has a greater predisposition to atherosclerotic cardiovascular disease, preoperative cardiovascular risk assessment with further noninvasive cardiac testing or coronary angiography, if indicated, should be considered.⁶¹

Preoperative spirometry, particularly the forced expiratory volume in 1 second (FEV₁), as an assessment of patients' suitability for pulmonary resection is essential. Measurement of the diffusing capacity of the lung for carbon monoxide (DLCO) provides complementary data to standard spirometry, particularly for patients with evidence of interstitial lung disease or exertional dyspnea. Generally, if a patient demonstrates a FEV₁ greater than 2 L (>60% predicted) or DLCO greater than 50% predicted, further evaluation of pulmonary

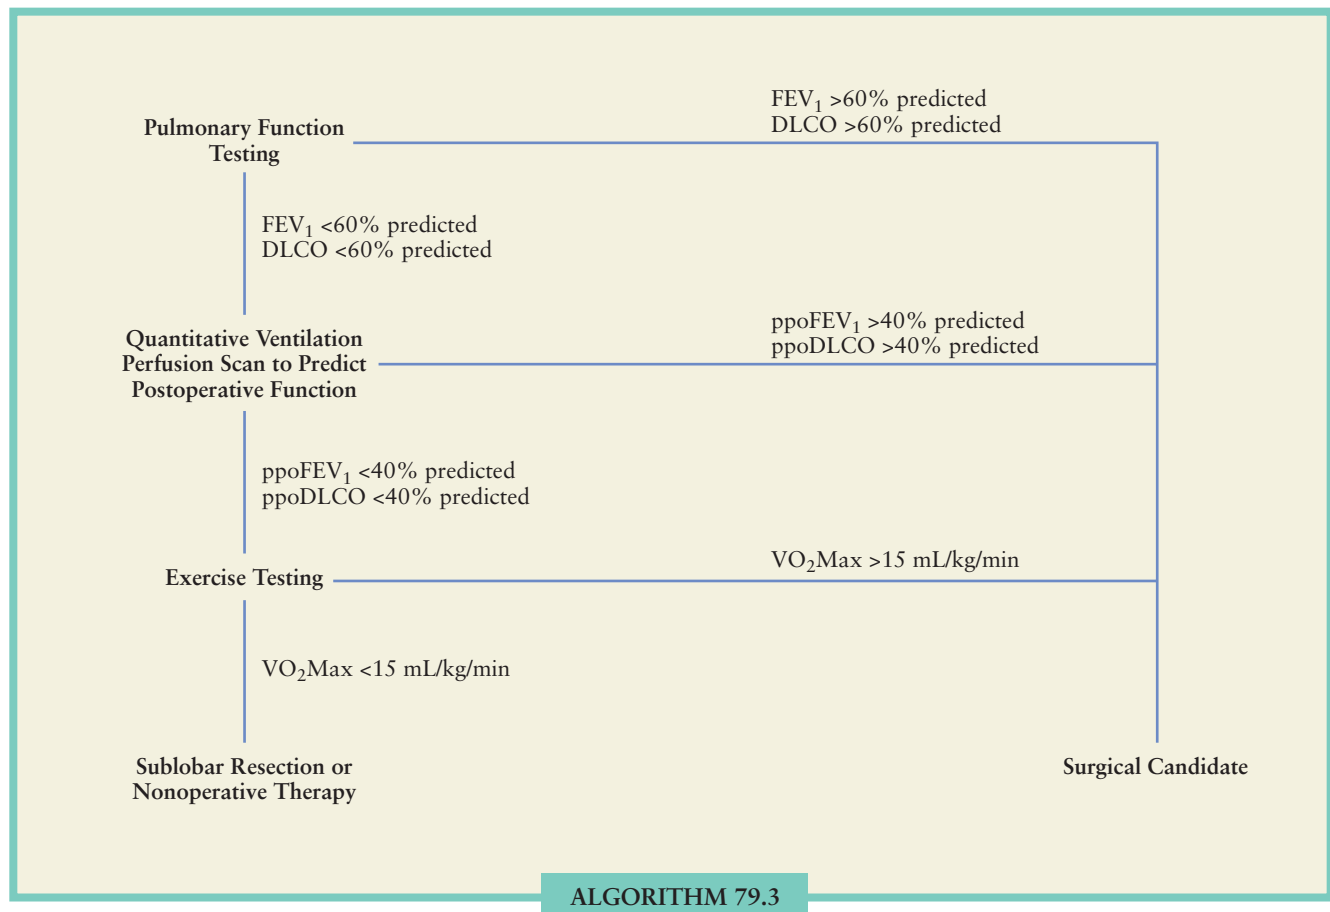

capacity prior to resection, including pneumonectomy, is not necessary.^{62,63} Patients with limited pulmonary reserve, including those with a FEV₁ less than 1.2 L (40% predicted) or DLCO 35% to 40% predicted, are at higher risk for significant morbidity or mortality following anatomic resection and should undergo further evaluation.⁶⁴

Preoperative room-air arterial blood gas testing can identify patients at greater risk for perioperative complications or death. In particular, patients with an arterial oxygen concentration less than 60 mm Hg, partial pressure of arterial carbon dioxide (PaCO₂) greater than 45 mm Hg, or oxygen saturation less than 90% may be at greater risk for pulmonary resection. Quantitative perfusion scanning allows the assessment of predicted postoperative (ppo) lung function in patients with marginal pulmonary function and can be calculated as follows: ppoFEV₁ (% predicted) = preoperative FEV₁ (% predicted) × (1 – fraction of total number of anatomic segments to be resected). Patients with a ppoFEV₁ less than 0.8 L, or 35% to 40% predicted, are likely at substantially increased risk for perioperative death or complication.^{65,66}

If available, further testing with formal cardiopulmonary exercise testing (CPET) in order to calculate maximal oxygen consumption (VO_{2max}) may allow further risk stratification in marginal patients. In several series, patients with a VO_{2max} less than 10 to 15 mL/min per kg were at very high risk for postoperative complications, whereas those with a VO_{2max} greater than 20 mL/min per kg underwent operation without complication or death.⁶⁶ These findings were corroborated by a recent cooperative group study (CALGB 9238) conducted to determine whether pulmonary resection could be accomplished safely in patients with peak exercise oxygen

capacity greater than 15 mL/min per kg, regardless of FEV₁. In this prospective study of 346 patients who underwent thoracotomy for NSCLC, there were 86 subjects whose peak exercise oxygen capacity was less than the threshold of less than 15 mL/min per kg, or 60% of predicted. This group experienced significantly more cardiorespiratory complications, respiratory failure, or death than the remaining subjects whose peak exercise oxygen capacity was greater than 15 mL/min per kg. From these data, the authors concluded that patients with peak exercise oxygen capacity greater than 15 mL/min per kg, even if the FEV₁ and/or DLCO were less than 70% predicted, could undergo pulmonary resection with curative intent.⁶⁷

Informal exercise testing, particularly stair climbing, may also aid the clinician in determining a patient's suitability for resection. Patients who are able to climb five flights of stairs will likely tolerate pneumonectomy, whereas those who cannot climb a single flight will likely not tolerate pulmonary resection. Furthermore, oxygen desaturation greater than 4% during exercise testing may also be an indicator for increased risk of perioperative complication. Careful preoperative physiologic assessment will allow the clinician to identify patients at increased risk for perioperative complication or death and allow such patients to make an informed decision regarding operation.⁶⁸ Measures to minimize postoperative complications, including aggressive efforts to encourage smoking cessation, pre- and postoperative chest physiotherapy, incentive spirometry, early extubation and mobilization, and the use of postoperative thoracic epidural analgesia, are important for all patients undergoing pulmonary resection, especially those with marginal pulmonary function (Algorithm 79.3).

Treatment

Pulmonary resection, with definitive tumor staging, remains the mainstay of treatment for stage I, stage II, and selected stage III NSCLC. The extent of resection—lobectomy, bilobectomy, or pneumonectomy—is determined by the location and size of the primary tumor and also whether adjacent bronchopulmonary nodes are involved. At operation, tumor extent can be determined with examination of the parietal pleura, pericardium, and mediastinal structures. Complete resection must achieve microscopically negative bronchial and vascular margins. Potential postoperative complications after pulmonary resection are listed in Table 79.6.

If a tumor extends directly into the chest wall, diaphragm, or pericardium, an en bloc resection of the adjacent involved structure should be performed with the pulmonary resection. Reconstruction is performed as necessary (Fig. 79.1). On the other hand, if extensive endobronchial involvement is present without involvement of the surrounding vascular or lymphatic structures, the tumor can sometimes be removed completely by lobectomy with segmental resection of the bronchus and/or pulmonary artery (bronchovascular sleeve resection), thus preserving lung function.

Patients with centrally located tumors should undergo sleeve lobectomy rather than pneumonectomy if complete resection can be achieved. Several institutional retrospective studies^{69–73} have demonstrated that operative mortality is reduced among patients undergoing sleeve lobectomy (0% to 5.2%) when compared with those patients undergoing pneumonectomy (1.7% to 8.9%). Moreover, overall 5-year survival is improved among patients undergoing sleeve resection, particularly among those with N0 or N1 nodal status. For peripherally located clinical stage I tumors, particularly among patients with limited pulmonary reserve or those at high risk from other comorbidities, segmental or nonanatomic “wedge” resection can be performed, although such patients are at greater risk for locoregional recurrence, as high as 25% to 50% in several reported series.^{74–77}

While noninvasive techniques for preoperative assessment of mediastinal nodes have improved, with the advent of combined CT-PET, clinical staging is still inaccurate. Therefore, nodal status should be confirmed by intraoperative mediastinal lymph

node sampling or mediastinal lymph node dissection. Accurate pathologic staging not only provides prognostic information but is also important in the decision on whether to proceed with adjuvant chemotherapy. Systematic sampling should include, for right-sided resections, at least one subcarinal, right paratracheal, and tracheobronchial angle lymph node each, and for left-sided resections, at least one subcarinal and para-aortic or aortopulmonary lymph node each, using standard nomenclature and numbering as depicted in Table 79.4. Several groups advocate complete mediastinal lymph node dissection, with en bloc removal of the nodal packets from the same levels as in systematic sampling.⁷⁸ Complete mediastinal lymph node dissection does not appear to confer increased perioperative morbidity,⁷⁹ but whether mediastinal lymph node dissection rather than sampling confers a survival advantage among patients undergoing major pulmonary resection remains controversial, and is one of the questions addressed in a recently completed multicenter clinical trial, Z0030, conducted by the American College of Surgeons Oncology Group (ACOSOG).

Survival

The long-term survival after resection for NSCLC is linked to the pathologic stage of disease. The overall 5-year survival rates are shown in Table 79.5. They range from 60% to 70% for stage I tumors, from 40% to 50% for stage II tumors, and from 15% to 30% for stage IIIA tumors. Nodal involvement has the strongest adverse influence on survival. Large peripheral tumors that extend directly into the chest wall without nodal involvement (T3N0) are associated with a 5-year survival rate of 40% after complete resection, whereas involvement of mediastinal nodes is associated with only a 20% survival rate. The status of the primary tumor has a lesser but still important effect on survival. Within stage I, for instance, T1N0 tumors are associated with a 5-year survival rate of 70%, substantially better than the 5-year survival rate of 60% associated with T2N0 tumors.

Some series suggest that histology also affects survival. In stage I or II NSCLC, the North American Lung Cancer Study Group (LCSG) consistently observed a better disease-free and overall survival for squamous cell cancer than for nonsquamous tumors.⁸⁰ Different adenocarcinoma subtypes, particularly in more advanced tumors, also appear to confer worse prognosis, but the influence of histology has not been reported uniformly in series to date.⁸¹ Delineation of tumor biology by more refined histologic and molecular analyses will be needed to define which patients might be at increased risk for recurrence.

Patterns of Recurrence. The predominant sites of relapse for all stages of NSCLC after resection are distant metastases. Approximately 30% of recurrences are locoregional with tumors of both squamous and nonsquamous histology.⁷⁶ For all stages of disease, the brain is the single most common site of relapse, and brain metastases occur more frequently with nonsquamous tumors. Other common metastatic sites include bone, ipsilateral or contralateral lung, liver, and the adrenal glands.^{76,82}

At least 60% of recurrences develop in the first 2 years after operation, and virtually all recurrences related to the original primary tumor occur within 5 years after surgery. The small proportion of patients with stage II or III disease who survive 5 years are likely to survive 10 years or more postoperatively. Most stage I patients, particularly those with T1N0 tumors, experience long-term survival. The North American LCSG followed 907 patients with T1N0 tumors for a minimum of 5 years after operation.⁸² Recurrences of the original primary tumor are uncommon after 5 years, and after that time the occurrence of new pulmonary cancers becomes the dominant problem. The risk for development of a second lung cancer in patients who survive resection of an NSCLC is estimated to be

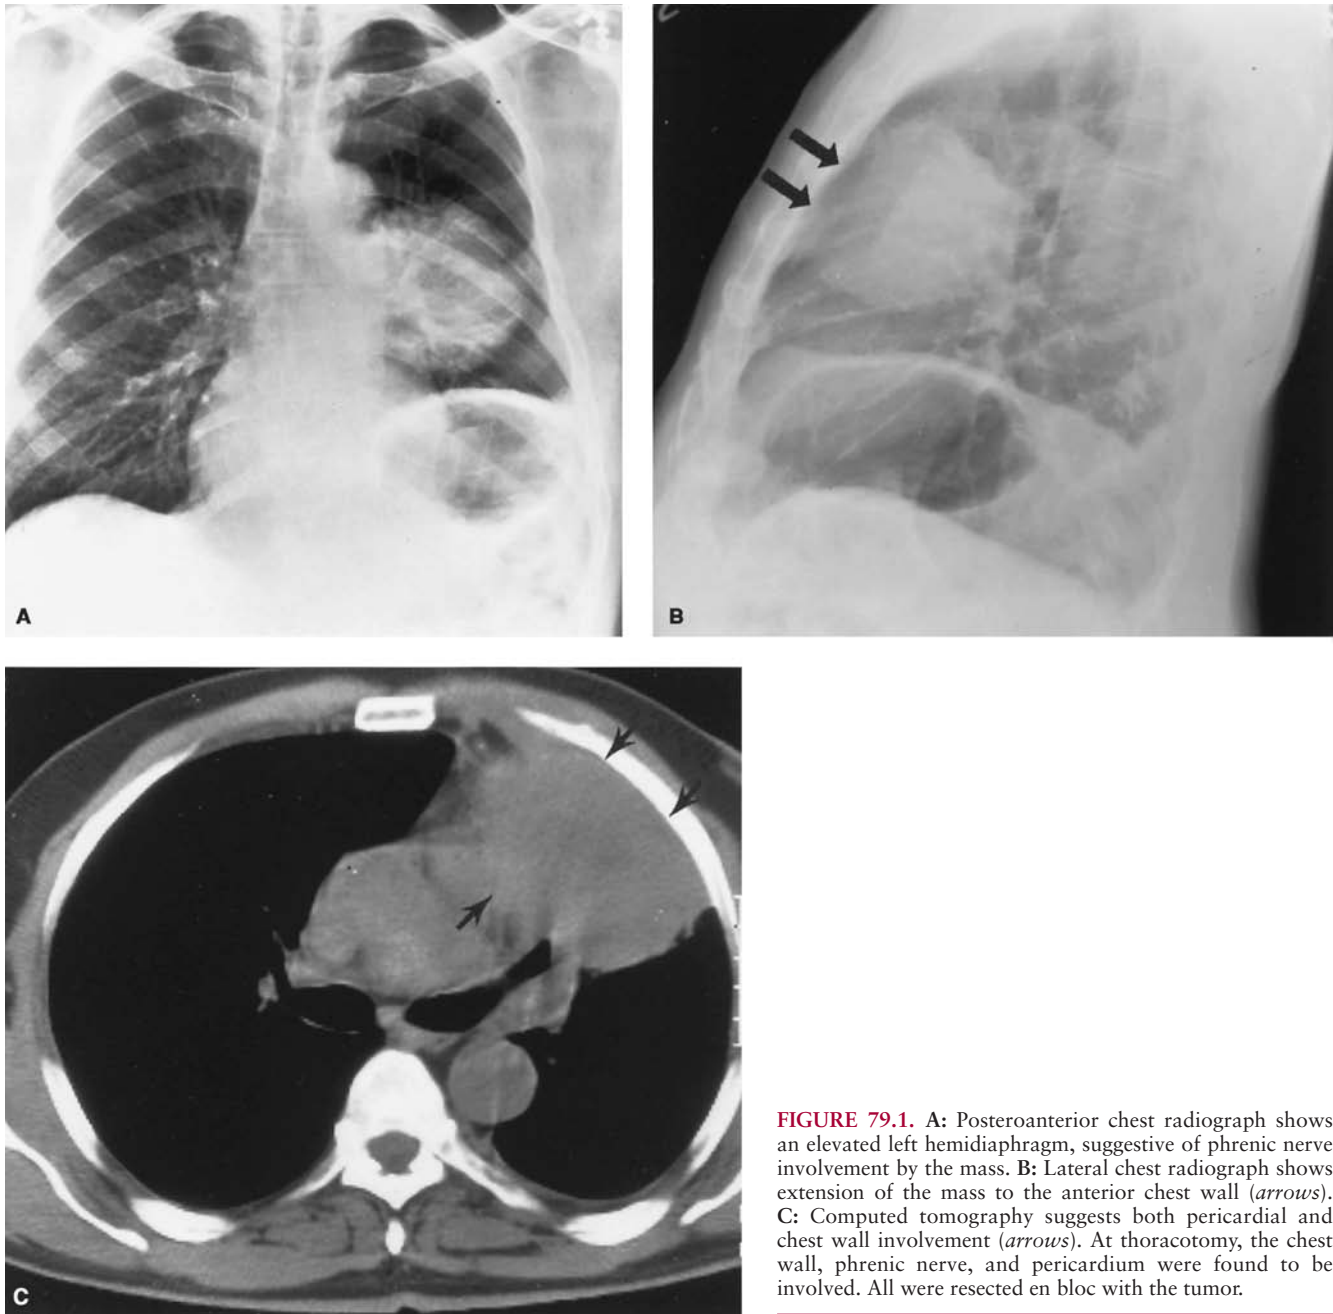

FIGURE 79.1. A: Posteroanterior chest radiograph shows an elevated left hemidiaphragm, suggestive of phrenic nerve involvement by the mass. B: Lateral chest radiograph shows extension of the mass to the anterior chest wall (arrows). C: Computed tomography suggests both pericardial and chest wall involvement (arrows). At thoracotomy, the chest wall, phrenic nerve, and pericardium were found to be involved. All were resected en bloc with the tumor.

2% to 3% per patient per year,⁸³ with a second lung cancer developing rarely in never-smokers at the time of initial resection and at rates of 1.8% per patient-year in former smokers and 2.7% per patient-year in current smokers.⁸⁴ Patients also face a consistent risk for the development of new, nonpulmonary primary cancers during the first 5 years after operation and thereafter. New, nonpulmonary malignancies develop in a wide variety of sites, but breast, colon, and prostate cancers are the most common.⁷⁶

These data underscore the importance of long-term follow-up after resection of early-stage NSCLC. Traditionally, most thoracic oncologists recommend oncologic surveillance for their lung cancer patients in coordination with a primary or referring physician every 3 to 4 months during the first 2 years after operation, then every 6 months the following 2 years and annually thereafter. Although there is no single modality to detect recurrence, follow-up should include a combination of history, physical examination, serial chest radiographs, and low-dose spiral chest CT. While the cost-effectiveness of this

approach is unproven,⁸⁵ cost decision analysis suggests that inclusion of annual surveillance chest CT could be beneficial, depending on factors such as patient age, cost of chest CT, rate of false-positive findings, and annual risk of a second primary lung cancer.⁸⁶

Adjuvant Therapy for Non-Small Cell Lung Cancer.

The risk for recurrent disease, even after resection of early-stage NSCLC, has led to efforts to improve overall survival rates through the use of adjuvant therapy, even though no specific method is available to identify which patients will relapse. Various types of adjuvant therapy have been tested, including immunotherapy,^{87–89} radiation, chemotherapy, and combined chemotherapy and radiation.

Radiation has been evaluated extensively as adjuvant therapy. Although early retrospective series suggested that postoperative radiation therapy (PORT) potentially improved overall survival,^{90–92} subsequent relatively small randomized trials comparing adjuvant radiation with no further treatment

failed to demonstrate any significant difference in overall survival.^{93–97} Distant metastases remained the most common form of recurrent disease and were not affected by postoperative radiation to the mediastinum. Several of these trials^{93,94,96,97} showed that radiation significantly decreased the risk for locoregional recurrence in tumors of all histologic types (Table 79.7). A meta-analysis of several randomized controlled studies of postoperative radiation therapy suggested an adverse effect on survival, particularly among patients treated

with PORT with early-stage (I or II) lung cancer.⁹⁸ Consequently, postoperative thoracic radiation appears to be appropriate for patients who are at high risk for locoregional recurrence such as those with bulky nodal disease or with evidence of residual tumor at surgical margins.

Because distant metastases are the predominant mode of relapse after resection of early-stage NSCLC, multiple randomized trials (Table 79.8) have been performed to determine if postoperative adjuvant chemotherapy improves survival.

^aThe stages are listed according to the 1997 international system for staging lung cancer.³

ANITA, Adjuvant Navelbine International Trialist Association; CAP, cyclophosphamide, doxorubicin, cisplatin; CCNU, J-12-chlorethyl-3-cyclohexyl-J nitrosourea; CDDP, cisplatin; COPAC, cyclophosphamide, doxorubicin, cisplatin, vincristine, lomustine; Cytosin, cyclophosphamide; DFS, disease-free survival; EP, etoposide, cisplatin; HN2, nitrogen mustard; IALT, International Adjuvant Lung Cancer Trial; M, mitomycin C; MTX, methotrexate; NS, not significant; no Rx, no adjuvant treatment; RT, radiation; UFT, tegafur plus uracil; Vnb, vinorelbine; VP, vindesine, cisplatin.

Early trials evaluated agents, including nitrogen mustards, Cytoxan, methotrexate, and nitrosourea, now known to have no activity in NSCLC.^{99–102} More recently, several studies have demonstrated that cisplatin-based chemotherapy regimens appear to provide a modest survival benefit. A meta-analysis of 9,387 patients entered into 52 randomized clinical trials showed a 5% survival benefit at 5 years for adjuvant cisplatin-based chemotherapy in comparison with surgery alone. Trials comparing adjuvant radiation with radiation plus chemotherapy showed an absolute survival benefit of 4% at 2 years in favor of combined-modality treatment.¹⁰³

Recent trials of adjuvant chemotherapy in patients with completely resected NSCLC appear to indicate a therapeutic benefit. Initial studies from the West Japan Study Group indicated that postoperative treatment with uracil-tegafur (UFT), a well-tolerated oral analogue of fluorouracil, confers a survival advantage.¹⁰⁴ Although a recent randomized phase III trial from this same group failed to demonstrate a survival advantage among patients with resected stage I adenocarcinoma or squamous cell carcinoma, subset analysis of patients with pT1N0M0 tumors indicated a significant improvement in overall survival.¹⁰⁵ The prolonged low-dose administration of fluorouracil, generally not considered to be an active drug against NSCLC, used in this trial appeared to have a significant antitumor effect.

The International Adjuvant Lung Cancer Trial evaluated the effect of cisplatin-based adjuvant chemotherapy on survival after complete resection of non-small cell lung cancer. A total of 1,867 patients with resected stage I, II, or III NSCLC were randomized to receive cisplatin-based chemotherapy, cisplatin-based chemotherapy and radiation, radiation alone, or no adjuvant treatment. Individual institutions administered additional chemotherapeutic agents at their discretion (“open-choice design”), with nearly half of the treated patients receiving cisplatin (100 mg/m²) and etoposide for three or four cycles. The total dose delivered of cisplatin was greater than 240 mg/m² for 73.8% of treated patients. Additional agents used were vinorelbine, vinblastine, or vindesine. Cisplatin dosing varied from 80 to 120 mg/m² per cycle, for a total expected dose of 300 to 400 mg/m². Statistically significant benefits were observed for both overall (absolute difference, 4.1%) and disease-free (absolute difference, 5.1%) survival at 5 years for patients treated with cisplatin-based chemotherapy, with or without adjuvant radiation.⁴ Planned radiotherapy did not appear to provide any added benefit. In subgroup analysis, the benefits of cisplatin-based adjuvant chemotherapy appeared to confer the greatest benefit upon patients with stage III NSCLC. In longer-term follow-up, disease-free survival hazard ratio remained improved at 0.88 (95% confidence interval [CI], 0.78–0.98; *p* = 0.02) for patients receiving adjuvant therapy at 7 years following operation, but the previously observed improvement in overall survival was no longer statistically significant with a hazard ratio of 0.91 (95% CI, 0.81–1.02; *p* = 0.10).¹⁰⁶

Several subsequent studies support the use of adjuvant chemotherapy, particularly in stage II and III lung cancer. In the National Cancer Institute of Canada-Clinical Trials Group (JBR.10), adjuvant treatment with vinorelbine and cisplatin resulted in prolonged overall and disease-free survival for patients with resected stage IB or II (excluding T3N0M0) NSCLC.⁵ These survival differences were demonstrated despite poor patient compliance, with only 50% of patients completing their prescribed regimen of adjuvant therapy.¹⁰⁷ In a phase III trial in which 840 patients with completely resected stage IB, II, and IIIA NSCLC were randomized to observation or adjuvant vinorelbine and cisplatin, the Adjuvant Navelbine International Trialist Association (ANITA) reported that risk-adjusted overall mortality was reduced significantly in subjects assigned to chemotherapy, with a hazard ratio of 0.80 (95% CI, 0.66–0.96; *p* = 0.017).⁶ Again, only 50% of patients receiving treatment completed the planned regimen.

The Cancer and Leukemia Group B (CALGB) 9633 trial reported 344 patients undergoing pulmonary resection for

T2N0M0 (stage IB) NSCLC, randomized either to adjuvant therapy with paclitaxel and carboplatin or observation. With a median follow-up of 74 months, no statistical difference in overall survival was observed between treatment groups, with a hazard ratio of 0.83 (95% CI, 0.64–1.08; *p* = 0.12) for patients receiving adjuvant therapy. Unplanned subgroup analysis indicated a significant survival benefit for patients with larger tumors (>4 cm), but as a group, adjuvant chemotherapy for stage IB NSCLC is not considered standard of care currently.¹⁰⁸

Notably, several of these trials have shown that approximately half of all patients actually received the planned dose of chemotherapy.^{109,110} It remains to be determined whether patients undergoing minimally invasive approaches to pulmonary resection can tolerate adjuvant chemotherapy better than similar patients recovering from open operations. In a recent report by Petersen et al., thoracoscopic lobectomy was found to improve the delivery of adjuvant chemotherapy.¹¹¹ In a series of 100 patients, 43 underwent thoracotomy and 57 had pulmonary resection performed by thoracoscopy. Those undergoing thoracoscopic resection were found to have a higher compliance rate. Chemotherapy doses were delayed in significantly fewer patients in the thoracoscopic group (18% versus 58%). Chemotherapy doses were reduced in 26% in the thoracoscopy group versus 49% in the thoracotomy group, which was also significant. In addition, a significantly higher percentage of patients received 75% or more of the planned regimen. There was no significant difference in the time to initiation of chemotherapy or toxicity.

Treatment of Stage III Disease

Stage III NSCLC indicates locoregionally advanced disease that encompasses several anatomic subsets that vary considerably in the likelihood that resection will provide durable oncologic benefit. Stage IIIB is generally considered unresectable. There is no role for resection for patients with T4 (stage IIIB) disease due to malignant pleural or pericardial effusion, infiltration of the heart or vertebra, or contralateral or supraclavicular nodal metastases (N3). However, several small series from specialized centers have demonstrated that surgery can be considered for selected patients with invasion of mediastinal structures such as the superior vena cava, left atrium, carina, or aorta, with consideration for induction chemoradiation, in order to “downstage” such tumors.^{112,113} These series indicate that complete resection is essential in order to obtain survival benefit from this approach.

Stage IIIA includes patients with extrapulmonary disease involving the ipsilateral hemithorax (i.e., T3N1 and T1–3N2). The management of patients with stage IIIA disease due to mediastinal nodal involvement (N2) continues to evolve, and is discussed in the following sections.

Role of Resection. The most controversial and complex part of the treatment of stage IIIA NSCLC is the management of patients with N2 disease. Reported 5-year survival rates after resection for N2 disease are usually 20% to 30% but range from zero to 40%. This variation reflects the extent of mediastinal nodal involvement, the T status of the primary tumor, and the ability to perform a complete resection. With respect to mediastinal nodal involvement, adverse prognostic factors include the presence of extracapsular nodal disease, multiple levels of involved lymph nodes, and superior mediastinal nodal metastases.^{114,115}

Historically, several series presented an inappropriately optimistic view of the benefit of resection for N2 disease because they focused on highly selected patients. The experience reported by Martini and Flehinger¹¹⁶ from Memorial Sloan-Kettering Cancer Center places resection for N2 disease in perspective because it examines the outcome of treatment of

all patients with N2 disease, not just a small subset. From 1974 to 1981, a total of 1,598 patients with NSCLC, of whom 706 had mediastinal nodal metastases, were seen by the thoracic service. Only 151 patients, or 21% of all patients with N2 disease, had technically complete resections of the primary tumor and all accessible mediastinal lymph nodes. The overall survival of these 151 patients was 29% at 5 years. Moreover, 33 of these 151 patients who had “clinical” N2 disease (mediastinal nodal involvement extensive enough to be visible on chest radiography or bronchoscopy) had only an 8% survival rate at 3 years. Thus, only 16.7% of all patients potentially benefited in the long term from resection. Overall survival was also influenced by the T status of the primary tumor; patients with T2 or T3 tumors fared significantly worse than those with T1 tumors. Based on these and other data, most surgeons consider for resection only those patients who have a T1 or T2 primary tumor and single-level intranodal N2 disease.

Rationale for Neoadjuvant Therapy. Although some patients with “minimal” N2 disease survive for long periods of time after resection, most have more extensive nodal involvement and do not benefit from surgery as their primary treatment. Until the 1980s, the standard treatment for such patients was radiation. The reported survival rates after radiation are harder to interpret than those after resection because most series include a mixture of stage IIIA and IIIB patients and do not define the precise extent of nodal involvement. Sequential trials by the Radiation Therapy Oncology Group (RTOG) showed that high-dose, continuous radiation yields the best chance of local control.¹¹⁷ Many attempts have been made to intensify radiation dose without increasing radiation side effects, either by altering radiation fractionation schemes or by using three-dimensional conformal treatment planning. On the whole, these efforts have led to minimal improvements in both local control and survival because most patients relapse in distant sites, just as they do after resection. For this reason, postoperative chemotherapy has been used as adjuvant therapy to surgery and radiation therapy in patients with N2 disease, although no benefit in survival has been shown.¹¹⁸ The poor long-term survival and the risk for distant metastatic disease prompted an investigation of neoadjuvant multimodality therapy for stage III NSCLC.

Two small randomized clinical trials further challenged the concept of resection as the primary treatment for any patient with N2 disease. Rosell et al.^{119,120} randomized 60 patients with stage IIIA NSCLC (16 of whom did not have N2 disease) to undergo resection or to receive three cycles of cisplatin-based chemotherapy followed by resection. The median survival of the patients who received preoperative chemotherapy was significantly longer (26 vs. 8 months) than the survival of patients who underwent only resection. A study of similar design from the M. D. Anderson Cancer Center corroborated these results.^{121,122} Both trials were stopped early because of highly significant differences between the two study arms. These two studies suggest that it is appropriate to consider all patients with N2 disease diagnosed at mediastinoscopy for induction chemotherapy. Unfortunately, because pretreatment mediastinoscopy was not mandated in either trial, some patients who did not have N2 disease were included. The results of these trials are not universally accepted because of the small numbers of patients enrolled, the lack of systematic pretreatment staging, and the unusually poor survival of the patients in the control (surgery-only) arms.

Early Trials of Neoadjuvant Therapy. The concept of preoperative therapy followed by resection (neoadjuvant therapy) dates back to 1955, when Bromley and Szur¹²³ used radiation (at an average dose of 47 Gy) to treat 66 patients before resection. At operation, no viable tumor was found in 29 of 62 (47%) patients, but 10 patients died of complications in the first month, and only two patients survived to 5 years after operation. At the time, the natural history of NSCLC was not well understood, the methods of staging before resection not

very accurate, and the risk for distant metastases not fully recognized. Effective chemotherapy did not exist and it was hoped that an approach that increased resectability might lead to better long-term survival. Thus, early neoadjuvant trials focused on the use of preoperative radiation.

Several subsequent studies further explored this approach.¹²⁴ All these trials were flawed by a lack of pretreatment staging, by the use of widely varying amounts of radiation, and by excessively long intervals between irradiation and resection. Nonetheless, it became apparent that aggressive local treatment did not improve long-term survival, even though radiation could sterilize tumor in a significant number of patients. The development of distant metastases in 50% to 80% of patients during or shortly after treatment underscored the need for systemic therapy in stage III NSCLC.

Recent Trials of Neoadjuvant Therapy. Because of a better understanding of the natural history of early-stage lung cancer and the revision of the international staging system in 1986, recent trials have defined more uniform patient populations, so that it has been easier to interpret trial results. Although many different treatment regimens have been used in neoadjuvant trials, they can be grouped into three major categories: (a) chemoradiation without resection, (b) chemotherapy followed by resection, and (c) chemoradiation followed by resection.

Trials of Chemoradiation without Resection. These trials cannot be equated with trials of neoadjuvant therapy that include resection because patients entered into nonsurgical trials are staged clinically without the benefit of mediastinoscopy. Therefore, nonsurgical trials include a mix of patients with stage IIIA and IIIB cancers, and they might even include some patients with earlier-stage disease who were thought erroneously to have stage III disease because of benign mediastinal adenopathy diagnosed only by CT.

With the acceptance of chemotherapy and radiation as standard treatment, attention has focused recently on the optimal means to deliver both modalities. A study suggests that concurrent treatment is superior to sequential chemoradiation. Furuse et al.¹²⁵ randomized 314 patients with stage III NSCLC to MVP (cisplatin, 80 mg/m² on day 1; mitomycin, 8 mg/m² on days 1 and 29; and vindesine on days 1, 8, 29, and 36) with concurrent split-course radiation or to MVP followed by standard radiation. Patients who received concurrent treatment had a significantly better response and survival.

The results of several phase III randomized trials comparing radiation alone with either sequential or concurrent chemotherapy and radiation are shown in Table 79.9. These trials confirm the feasibility of combined-modality treatment and overall have shown that patients receiving chemoradiation have a better survival than those receiving either standard fractionated or hyperfractionated radiation alone. In most studies, the addition of chemotherapy improved median survival from between 9 and 10 months to 14 months and 5-year survival from 5% to between 15% and 20%. The somewhat variable results among these trials are related to several factors, including differences in total radiation dose and method of administration (split vs. continuous course); differences in chemotherapy dose, especially with respect to cisplatin; and differences in patient selection based on staging criteria.

Trials of Neoadjuvant Therapy with Resection. These trials have used two different treatment strategies: induction chemotherapy alone or concurrent chemoradiation before resection. The rationale for chemotherapy alone as induction treatment is that it potentially allows the use of a more intense dose and the use of some drugs, such as mitomycin, that cannot be administered in conjunction with radiation. Proponents of this approach also believe that chemotherapy is as effective as induction treatment as is combined chemoradiation, and that separating the two modalities allows irradiation to be

used postoperatively, when a higher total dose can be given. Proponents of concurrent preoperative chemoradiation believe that this approach provides adequate systemic treatment of micrometastatic disease and more effective control of bulky primary and mediastinal tumors.

Neoadjuvant Trials of Chemotherapy Alone before Resection.

One of the best-known early trials to demonstrate the feasibility of combining induction chemotherapy with subsequent pulmonary resection in patients with stage III NSCLC was developed by Martini et al.¹²⁶ at Memorial Sloan-Kettering Cancer Center. In 1984, they initiated a trial of high-dose, cisplatin-based (120 mg/m²) chemotherapy followed by resection for patients with clinical N2 disease. Vindesine or vinblastine and subsequently mitomycin were added to form the so-called “MVP” regimen. Postoperative radiation was given to patients who had persistent mediastinal nodal tumor at thoracotomy, and all patients received two additional cycles of chemotherapy postoperatively. In 136 patients treated from 1984 to 1991, the major response rate to induction chemotherapy was 77% (105/136), and the complete resection rate was 65% (89/136). A complete pathologic response was noted in 19 patients (21%) at the time of resection. The overall survival at 5 years was 17% and the median survival was 19 months: a distinct improvement over the historical survival for this group

of patients. Seven treatment-related deaths (5%) occurred in this study, five of which were postoperative.

A phase II trial, reported by the CALGB in 1995, of induction chemotherapy enrolled 74 patients, treated with two cycles of cisplatin (100 mg/m² on days 1 and 29) and vinblastine (5 mg/m² per week) without mitomycin followed by resection for patients with mediastinoscopy-proven stage IIIA N2 disease.¹²⁷ In addition, two cycles of chemotherapy and 59.4 Gy of radiation were given postoperatively. Sixty-three patients (85%) had either an objective response or stable disease after induction therapy and underwent thoracotomy, with an operative mortality rate of 3.2%. Twenty-three patients (37% of thoracotomies, 31% of all patients) had a complete resection, with 3-year survival of 46%. The overall 3-year survival was 23%. The lower resectability rate in this trial than in the study performed at Memorial Sloan-Kettering potentially reflects both the multi-institutional nature of this trial and the use of a less intensive chemotherapy regimen (primarily because of the omission of mitomycin). However, the overall long-term survival appears similar for the two trials.

Trials of Induction Chemoradiation Followed by Resection.

The second approach to combined-modality therapy and resection for stage III NSCLC has been to combine chemotherapy and radiation preoperatively (Table 79.10).

^aFrom survival curve.

^bSurvival data for patients found to be resectable at thoracotomy.

This strategy aims to control micrometastatic disease while utilizing the synergism of concurrent radiation and chemotherapy to reduce tumor bulk in the primary site and mediastinum. In one of the first trials of this type, performed by the North American LCSG, 39 patients with stage III NSCLC received three cycles of chemotherapy with cyclophosphamide, doxorubicin, and cisplatin (CAP) and 1,500 cGy of radiation in 300-cGy fractions given concurrently with cycles 2 and 3 of the chemotherapy. The overall response rate to induction therapy was 51% (20/39), and 33% (13/39) of patients had a complete resection at thoracotomy. However, the overall 2-year survival was only 8%, with a median survival of 11 months. No treatment-related deaths occurred.¹²⁸

The LCSG subsequently performed another phase II induction trial of cisplatin, 5-fluorouracil, and partially concurrent low-dose radiation (3,000 cGy in 15 fractions) in 85 patients with stage IIIA N2 or stage IIIB NSCLC.¹²⁹ Although the cisplatin dose in this trial was higher than in the previous study (75 instead of 60 mg/m² per dose), the overall response rate and complete resection rates were similar (56% and 34%). The median survival was 13 months. Four of 54 patients (7%) died postoperatively.

Faber et al.¹³⁰ at Rush-Presbyterian performed two sequential phase II neoadjuvant trials of 5-fluorouracil and low-dose cisplatin (60 mg/m²) plus 4,000 cGy of split-course radiation administered concurrently with the four cycles of induction chemotherapy. The second group of 74 patients also received etoposide in addition to the cisplatin and 5-fluorouracil. Of the 130 patients entered into these trials, 85 were candidates for surgery after induction therapy, and 62 (73%) underwent thoracotomy. The complete resection rate was 68% (58/85), and the overall survival rate was 40% at 3 years, with a median survival of 22 months. The induction therapy was associated with significant toxicity, but only one treatment-related death occurred. The operative mortality rate was 5% (3/62). The excellent results of these trials may reflect the inclusion of some patients who did not have N2 disease but were considered at that time to have stage III NSCLC by virtue of T3 (chest wall) N0 tumor status.

A neoadjuvant trial of similar design was performed by the CALGB in which high-dose cisplatin (100 mg/m²), vinblastine, and 5-fluorouracil were given with 3,000 cGy of continuous radiation in 15 fractions to patients with stage IIIA disease.¹³¹ The overall response rate was 51% (21/41), and the complete resection rate was 61% (25/41). The median survival was 15.5 months. Significant toxicity occurred, and treatment-related mortality was high at 15% (6/41).

The largest reported phase II neoadjuvant trial of concurrent chemotherapy and radiation was a multi-institutional study performed by the Southwest Oncology Group.¹³² Both stage IIIA and stage IIIB patients were entered, although notably, pathologic documentation of the initial tumor stage, usually by mediastinoscopy, was required. The induction regimen included two cycles of cisplatin (50 mg/m² on days 1 and 8) and etoposide with 4,500 cGy of concurrent radiation in 25 fractions. All patients underwent thoracotomy unless their disease progressed. The objective response rate to induction therapy in the 126 eligible patients was 59%. The resectability rates were 85% for the IIIA N2 group and 80% for the IIIB group. Nearly two thirds of the patients had no viable tumor or only minimal residual foci of tumor in their surgical specimens. The 3-year survival rate was 27% for the IIIA group and 24% for the IIIB group, with median survival of 13 and 17 months, respectively. The best predictor of survival after surgery was the absence of tumor in the mediastinal nodes at surgery (3-year survival of 44%). The majority of recurrences were distant, and the brain was the single most common site. The operative mortality rate was 6%, and the overall treatment-related mortality was 10%. An important finding of SWOG 8805 was that survival was the same for patients with stage IIIB NSCLC by virtue of T4 tumor status and patients with stage IIIA

N2 disease. Patients with N3 disease had a poor overall survival. Importantly, the long-term follow-up of this study showed that the survival rates at 3 years were sustained at 6 years.¹³³

Important differences between the Southwest Oncology Group trial and earlier neoadjuvant trials were the careful documentation of pretreatment stage, the use of a higher dose of continuous radiation (4,500 cGy rather than 3,000 cGy of continuous or 4,000 cGy of split-course radiation), and the fully concurrent manner in which the chemotherapy and radiation were administered. Early attempts to intensify this therapeutic approach by increasing or accelerating the radiation were associated with unacceptable toxicity. Two small single-institution trials illustrate this problem. Yashar et al.¹³⁴ treated 36 patients who had stage IIIA N2 disease with two cycles of cisplatin (25 mg/m² per day for 4 days) and etoposide and 55 Gy of concurrent radiation. All patients underwent exploratory thoracotomy, and 31 (86%) underwent resection, 27 with pneumonectomy. Although the overall 3-year survival rate was 34%, two operative deaths (5.6%) occurred, six patients required prolonged intubation because of postoperative acute respiratory distress syndrome (ARDS), and a bronchial stump leak developed in three patients.

In the second study, Fowler et al.¹³⁵ treated 13 patients who had stage IIIA N2 disease with two cycles of cisplatin (20 mg/m² per day for 4 days), 5-fluorouracil, and etoposide and 60 Gy of concurrent radiation in 30 fractions. Six patients then underwent lobectomy, and seven patients underwent pneumonectomy. The complication rate was unacceptably high; ARDS developed in one of the lobectomy patients and in five of the seven pneumonectomy patients, and was fatal in two patients. Bronchial stump leaks developed in three pneumonectomy patients, of whom one died. The trial was closed prematurely after 13 patients had been accrued because of the excessive morbidity and mortality. An additional 27 patients who received the same induction therapy but did not undergo thoracotomy tolerated the treatment without major problems.

Two additional trials have tested concurrent induction chemoradiation in stage III NSCLC. Milstein et al.¹³⁶ conducted a phase II trial in which 36 patients (10 with T3N0 or T3N1 disease and 11 with IIIB disease) received two cycles of cisplatin (25 mg/m²) and etoposide plus concurrent radiation to 50 Gy during 28 sessions. Twenty-four patients (21 with IIIA and three with IIIB disease) underwent thoracotomy, with complete resection in 20 (86%). Three of the 21 IIIA patients had complete tumor sterilization. The overall survival at 2 years was 39% (57% for resectable patients and 15% for unresectable patients), and the median survival was 15 months. One death from sepsis occurred during the induction treatment, and two postoperative deaths resulted from ARDS and bronchopleural fistula. This attempt to intensify induction chemoradiation by increasing the dose of radiation was not successful.

One study from the University of Texas M. D. Anderson Cancer Center addresses the question of whether radiation augments the benefit of induction chemotherapy before resection.¹³⁷ This retrospective review identified 107 patients who underwent resection for stage IIIA disease. Patients had been treated with induction chemotherapy (55 patients) with cisplatin (100 mg/m²) or carboplatin/Taxol; concurrent chemoradiation (15 patients) with cisplatin (75 mg/m²) and vinblastine plus daily radiation to 60 to 63 Gy; or concurrent chemoradiation (37 patients) with cisplatin (50 mg/m²) and etoposide plus hyperfractionated radiation to 69.6 Gy. Postoperatively, 35 patients treated with induction chemotherapy received adjuvant radiation therapy.

A North America Intergroup clinical trial sought to determine whether neoadjuvant therapy including resection is superior to nonsurgical treatment with chemotherapy and higher-dose radiation in patients with stage IIIA NSCLC. In the Intergroup 0139/RTOG 9309 trial,¹³⁸ patients with proven pN2, stage IIIA NSCLC were randomized to receive neoadjuvant chemotherapy with concurrent thoracic radiation therapy (TRT) followed by operation or continuation with definitive TRT.

Of 429 patients accrued over 92 months, 392 patients were considered eligible and were treated with cisplatin (50 mg/m²) on days 1 and 8 and etoposide (50 mg/m²) on days 1 through 5 every 3 weeks for two cycles, as well as 45 Gy TRT. Patients randomized to resection ($n = 201$) underwent operation 4 to 6 weeks later. Patients randomized to definitive radiation ($n = 191$) continued without break to a total of 61 Gy. Following operation or completion of TRT, consolidation with two cycles of cisplatin and etoposide was given. Of note, less than two thirds of patients undergoing operation received consolidation treatment, compared with over 75% of patients receiving chemoradiation only. There was no mortality in either group during induction chemoradiation. Surgical mortality was 7%, with 12 of 14 deaths occurring in patients undergoing pneumonectomy.

Progression-free survival (PFS) was improved from a median of 11.8 months to 13.4 months, and 3-year PFS from 19% to 27% with the addition of surgery. There appeared to be improved local control with the addition of surgery, with local failure occurring in only 5% of surgically treated patients compared with 16% in the nonsurgical group, although this was not statistically significant. However, no statistically significant differences were seen in overall survival, with 3-year survival of 34% and 37% for the chemoradiation alone and chemoradiation and surgery groups, respectively. Survival for patients undergoing complete resection in this study has not yet been published. This study indicated that carefully selected patients with N2-positive stage IIIA NSCLC can be treated with multimodality therapy including resection.

The role of surgery for patients whose tumors appear to require pneumonectomy remains controversial as well. In the recently published German Lung Cancer Study Group trial, patients were randomized to induction chemotherapy (cisplatin and etoposide) followed by chemoradiation (concurrent carboplatin and vindesine) followed by resection, or induction chemotherapy followed by surgery alone. Of 524 patients deemed eligible, randomized, and started on treatment, 296 underwent operation and 272 underwent tumor resection. In an intention-to-treat analysis of patients eligible and randomized to different arms of this study, no differences in progression-free or overall survival were observed between the treatment groups. Patients receiving preoperative chemoradiation were more likely to achieve complete resection among those with resectable tumors (98/131 vs. 84/141, $p = 0.008$), and were more likely to have evidence for mediastinal downstaging and pathologic response, but again with no significant difference observed in progression-free or overall survival. Of 104 patients who required pneumonectomy, including 39 right sided, for resection, mortality was slightly greater among patients treated with preoperative chemoradiation (7/50 vs. 3/54), but this was not statistically significant.¹³⁹ Parenchymal-preserving bronchoplastic techniques also can be considered for those patients who might otherwise require pneumonectomy.¹⁴⁰ Whether such technically challenging approaches can be undertaken in the setting of recent radiation therapy remains to be established.

Stimulated by the promising results of the Southwest Oncology Group 8805 trial for patients with T4 disease, Grunewald et al.¹¹³ performed a phase II trial of similar design for stage IIIB T4 NSCLC. The induction regimen consisted of cisplatin (100 mg/m²), 5-fluorouracil, and vinblastine with 45 Gy of concurrent hyperfractionated (twice daily) radiation. Of 25 patients enrolled, 16 were subsequently eligible for surgery, and 12 had complete resection. No induction treatment-related or operative deaths occurred. This study confirms that complete resection after induction therapy is feasible in a significant number of stage IIIB T4 tumors, a subset of stage IIIB tumors previously considered inoperable under any circumstances.

for the treatment of stage III NSCLC. Most studies show improved rates of resectability and survival in comparison with the historical experience for resection or radiation alone. The optimal treatment approach to these locally advanced tumors has not yet been fully defined, especially because neoadjuvant trials vary with respect to eligibility criteria, inclusion of both stage IIIA and stage IIIB tumors, accuracy of pretreatment staging, and type of induction regimens. Moreover, the response, resectability, and survival rates are not uniformly reported. In some cases, instead of reporting results as a percentage of the total number of patients entered into the study, the authors report resectability rates as a percentage of the patients with a radiographic response, and only the survival rates of patients who underwent resection are emphasized.

The potential toxicity of neoadjuvant regimens should not be overlooked. Induction regimens in which high-dose cisplatin (≥ 100 mg/m²) or radiation doses of 4,000 to 4,500 cGy are used have been well tolerated, but radiation doses of 5,500 cGy or higher have been associated with an excessive risk for postoperative ARDS and bronchial stump leak. Good response rates have been achieved with chemotherapeutic agents including paclitaxel, docetaxel, gemcitabine, and carboplatin, and they are better tolerated by patients. Determining the contribution of these agents in combined-modality therapy will require further trials, especially as the major form of relapse continues to be distant metastatic disease.

7 Future Directions. In addition to new chemotherapeutic agents, new radiation techniques, such as hyperfractionated or accelerated schedules, also merit further exploration in neoadjuvant trials with concurrent chemotherapy. Adelstein et al.,¹⁴¹ from the Cleveland Clinic, conducted a study in which 45 patients with stage IIIA or IIIB NSCLC received induction cisplatin, paclitaxel, and 30 Gy of accelerated hyperfractionated radiation therapy (1.5-Gy fraction twice daily). Surgery was then performed approximately 4 weeks after induction. The overall response rate was 54%. Forty patients (89%) proceeded to surgery, and 32 patients (71%) underwent complete resection. Five complete pathologic remissions were seen. Fourteen patients overall were downstaged. Patients received a consolidation dose of chemotherapy and additional radiation to a total of 60 to 63 Gy. The 2-year relapse-free survival rate was 47%, and the 2-year survival rate was 65%. No apparent therapy-related deaths occurred, but the toxicity was high, with 89% of patients experiencing significant mucositis and 20% experiencing esophagitis of grade 3 or worse. Three-dimensional conformal therapy permits higher radiation dosing (>70 Gy) of the tumor while sparing surrounding normal lung in order to provide improved local control.^{142,143}

The management of stage III NSCLC is complex and still evolving. Many trials indicate that resectability and survival rates are probably improved with the use of combined-modality therapy than with radiation or resection alone. Regimens incorporating high-dose cisplatin with or without moderate-dose radiation have achieved the best results with acceptable levels of toxicity. Careful patient management leads to complete resection, and the operative risk is comparable with that of standard pulmonary resection. Importantly, combined-modality treatment requires close collaboration among medical oncologists, radiation oncologists, surgeons, pulmonologists, and anesthesiologists. In the future, three key areas warrant further investigation: (a) the optimal combination and sequence of newer, less toxic chemotherapeutic agents and a variety of new radiation techniques; (b) whether concurrent chemoradiation is superior to chemotherapy alone as preoperative induction therapy; and (c) the identification of the molecular features that dictate tumor response to different chemotherapeutic agents, allowing a more individualized selection of induction treatment regimens, which may lead to improved long-term outcomes.

6 Current Status of Neoadjuvant Therapy and Resection.

Taken as a whole, neoadjuvant therapy trials have demonstrated the feasibility of induction chemotherapy and resection

FIGURE 79.2. Gross figure of a squamous cell carcinoma showing a superior sulcus tumor (*Pancoast tumor*) arising from apex of the right lung. (Reproduced with permission from Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Superior Sulcus Tumors. Tumors of the superior sulcus (Fig. 79.2), described in detail by H. K. Pancoast in 1932,¹⁴⁴ represent an uncommon (3%) and challenging subset of NSCLC. Tumors frequently involve the brachial plexus, subclavian vessels, or spine and typically fall into two categories: T3N0–1 (stage IIB or IIIA) or T4N0–1 (stage IIIB).¹⁴⁵ Until the 1950s, these tumors were felt to be almost universally fatal, with no benefit provided by resection. In 1961, Shaw and Paulson demonstrated that preoperative thoracic radiation followed by resection was potentially curative.¹⁴⁶ For the subsequent 30 to 35 years, reports demonstrated 5-year survival of approximately of 25% to 30%. In a single-institutional experience spanning 24 years, during which 225 patients underwent thoracotomy at Memorial Sloan-Kettering Cancer Center, 5-year survival for patients undergoing resection for stage IIB, IIIA, and IIIB superior sulcus tumors was 46%, 0%, and 13%, respectively.¹⁴⁷ In this retrospective study, the mode of preoperative therapy, with radiation and/or chemotherapy, or adjuvant therapy did not appear to affect survival, which was influenced only by completeness of resection and tumor and nodal status in a multivariate analysis. As in other retrospective series, locoregional recurrence was the most common form of relapse, occurring in 40% of patients.¹⁴⁸

Spurred by reports of the apparent success of neoadjuvant chemotherapy and thoracic radiation in achieving improved local control and survival for patients with locoregionally advanced NSCLC, the Southwestern Oncology Group coordinated a phase II trial, the first prospective, multicenter trial (SWOG 9416/Intergroup 0160) for superior sulcus tumors.¹⁴⁹ Of 111 patients eligible, including 31 patients with T4 disease, 102 completed induction chemoradiation and 95 were eligible for operation. Patients with mediastinal lymph node metastases (N2) were excluded from this trial. Of the 88 patients

who underwent thoracotomy, over 90% had a complete resection, with 65% of patients demonstrating complete pathologic response (R0) or minimal residual disease (R1). Overall treatment mortality was 4.5%, including an operative mortality of 2.4%. Of note, intracranial and other distant metastases were more common (22% each) than locally recurrent disease only (11%). Overall 2- and 5-year survival was 55% and 41% for all patients enrolled, and 70% and 53% for patients with a complete response, respectively.

NEUROENDOCRINE TUMORS

Neuroendocrine tumors of the lung include a varied group of lesions ranging from tumors with low-grade malignant potential (typical carcinoid) to SCLC, which is among the most rapidly growing and aggressive of human tumors. Between those two extremes, atypical carcinoid and large cell neuroendocrine carcinoma have been defined.¹⁵⁰

Typical and Atypical Carcinoid Tumors

Carcinoid tumors, which are neoplasms with a low-grade malignant potential, account for about 2% of lung tumors in the United States. They arise from neuroendocrine stem cells of the bronchial epithelium and are classified as either typical or atypical. Histologically, typical carcinoids consist of uniform polygonal cells with round nuclei and fine granular chromatin (Fig. 79.3). Mitotic figures are rare. Atypical carcinoids show increased mitotic activity, nuclear pleomorphism, areas of disorganized architecture, and tumor necrosis¹⁵¹ (Fig. 79.4).

Carcinoid tumors occur equally in both sexes and at a median age of 55 years. Half of patients present with pulmonary symptoms, including hemoptysis, dyspnea, and recurrent or persistent pneumonitis, because 40% of lesions are centrally located in the main or lobar bronchi (Figs. 79.5 and 79.6). The lesions may be diagnosed by bronchoscopy, appearing as pink or purple friable endobronchial masses covered by intact epithelium. In the other half of patients, carcinoid tumors are diagnosed when radiologic abnormalities are detected on a chest roentgenogram as part of a routine examination.¹⁵²

Lymph node metastases occur in approximately 10% to 15% of patients at diagnosis but are more frequent in atypical carcinoids. The carcinoid syndrome is associated with bronchial carcinoids in only 2% of cases, usually in patients

FIGURE 79.3. Typical carcinoid tumor of the lung. A microscopic view shows ribbons of tumor cells embedded in a vascular stroma. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

with metastatic disease, particularly of the liver. The most common sites of metastases are lung, bone, liver, adrenals, and brain.¹⁵²

The standard treatment for bronchial carcinoid is complete resection, regardless of the presence of nodal involvement, with mediastinal lymph node sampling or dissection.¹⁵³ Lobectomy is required in about 50% of patients. Lesser resection (segmentectomy, sleeve resection) is adequate for complete resection in about 20% of patients. Endoscopic resection is invariably associated with local recurrence and should be used only as a

FIGURE 79.6. Gross figure of a resected carcinoid tumor cut in cross section to show invasion through the bronchial cartilage. (Reproduced with permission from Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

palliative maneuver in patients whose general medical condition precludes thoracotomy and pulmonary resection.¹⁵²

The long-term survival rate after resection exceeds 90% in patients with typical carcinoids, even when hilar or mediastinal nodal metastases are present. In contrast, patients with atypical carcinoids have a 5-year survival rate of 60% after complete resection. The outcome is more closely linked to histology than to tumor size, location, or nodal involvement. Recurrence is more frequent with tumors larger than 3 cm and in patients who present with lymph node metastases.¹⁵²

Large Cell Neuroendocrine Carcinomas

Large cell neuroendocrine carcinoma is characterized by the microscopic features of neuroendocrine tumors, but the tumor cells are large, have a high mitotic rate, and frequently show necrosis^{150,151} (Fig. 79.7). According to Travis et al.,^{154,155} large cell neuroendocrine carcinomas are related to smoking, as is SCLC, and are high-grade tumors with 5- and 10-year survival

FIGURE 79.5. Gross figure of a carcinoid tumor protruding into the bronchial lumen. (Reproduced with permission from Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

rates of 27% and 9%, respectively, despite complete resection. Few data are available concerning adjuvant therapy. For the time being, the management of large cell neuroendocrine carcinoma is identical to that of NSCLC.¹⁵⁶

Small Cell Lung Cancer

Small cell carcinoma of the lung has the most aggressive clinical course of any type of pulmonary tumor and is often widely disseminated by the time of diagnosis. In contrast to non-small cell tumors, these lesions are notably responsive to chemotherapy and are rarely within the domain of the surgeon. The staging system for SCLC was developed by the Veterans Administration Lung Cancer Staging Group and divides patients into those with limited and those with extensive disease. This distinction was first based on what could be encompassed by a tolerable radiation portal. After clarification by the International Association for the Study of Lung Cancer, limited disease includes patients with tumors confined to one hemithorax and regional lymph nodes (hilar, ipsilateral, and contralateral mediastinal nodes, and ipsilateral and contralateral supraclavicular nodes) as well as patients with ipsilateral pleural effusion, regardless of whether the cytology is positive or negative. On the other hand, both pericardial and bilateral pulmonary involvement are considered extensive disease.¹⁵⁷

Common sites of distant metastases are bone, liver, bone marrow, and the central nervous system, and therefore the metastatic evaluation includes a bone scan and CT of the chest, abdomen, and brain. Some oncologists also perform bone marrow biopsies, but because the marrow is the sole site of extensive disease in fewer than 5% of patients, biopsies are usually judged unnecessary. After the staging process, approximately 30% to 40% of patients are found to have limited disease.

For patients with limited disease, response rates of 85% to 90% and complete response rates of 50% to 60% can be expected with the combination of etoposide and cisplatin and radiation therapy.¹⁵⁸ The median survival is 18 to 24 months, and the 2-year survival rates are 40% to 50% (5% more than before the use of radiation therapy).^{159,160} In extensive SCLC treated with chemotherapy, response rates reach 75% to 85%, although complete response is seen in only 15% to 25% of patients. The median survival is between 7 and 11 months, with a 2-year survival near zero. The prognosis in SCLC depends primarily on the anatomic extent of disease, but after a review of prognostic variables in its 2,580-patient SCLC database, the Southwest Oncology Group determined that the two-stage system should be extended into a four-stage system, with serum lactate dehydrogenase level, age, and pleural effusion used as additional staging criteria.¹⁶¹

The small numbers of patients with SCLC seen by the surgeon represent fewer than 10% of all patients with SCLC. They have peripheral tumors with no nodal involvement or only hilar nodal involvement, which would be classified as T1–2 N0–1 tumors in the NSCLC staging system. In the past, such tumors were often diagnosed at exploratory thoracotomy for an asymptomatic coin lesion, but with the increasing use of diagnostic percutaneous needle aspiration, more patients with early-stage SCLC are now identified preoperatively. Such patients should be evaluated in conjunction with a medical oncologist, and resection should be considered after distant disease has been excluded by a complete metastatic evaluation. For such cases, it has been suggested that the TNM classification be used in future trials and studies.¹⁶²

Retrospective series have demonstrated a 5-year survival rate of 30% to 50% after resection of T1 N0 or T2 N0 SCLC.^{162–164} Because of the propensity for small cell cancers to disseminate, adjuvant chemotherapy has traditionally been given to patients after resection, even though, by virtue of the small numbers of patients available, no prospective randomized trials have demonstrated whether this is of benefit.¹⁶⁴

Relapse at the primary site, which is a problem for most patients with limited-stage SCLC, is distinctly uncommon after complete resection of these early tumors.¹⁶⁵ Radiation therapy to the chest has been suggested after surgically complete resection, but because insufficient information is available in the literature and local relapse is uncommon, it cannot be considered a standard treatment.^{163,164}

Because the role of resection in patients with mediastinal nodal involvement (N2 disease) is questionable, mediastinoscopy should be considered mandatory to exclude mediastinal nodal disease.¹⁶⁶ This should ideally be performed separately from thoracotomy because it can be difficult for the pathologist to diagnose small cell cancer on a frozen section. The intraoperative management of SCLC is not significantly different from that of NSCLC, and an incomplete resection does not benefit the patient.

The addition of resection after a response to induction chemotherapy has been proposed by some surgeons to cure a small number of patients with limited SCLC without mediastinal involvement.¹⁶⁷ To date, the LCSG has performed the only prospective randomized trial evaluating the role of surgery in limited SCLC.¹⁶⁸ All patients enrolled in that study received chemotherapy, and those in whom at least a partial response was achieved were randomized to undergo or not undergo surgery. Because the survival rate was the same in both groups, this trial did not support the addition of pulmonary resection to the multimodality treatment of SCLC. Finally, the occurrence of a second primary lung carcinoma after treatment for SCLC has been reported in the few patients with prolonged survival. It should not be assumed that the new tumor is of small cell histology, and these patients should be evaluated for the possibility of resection.¹⁶⁹ The average risk for the development of a second lung cancer in patients who survive SCLC is approximately 6% per patient per year.⁸³

BRONCHIAL GLAND CARCINOMAS

Bronchial gland carcinomas are rare primary tumors of the lung. They constitute about 1% of all lung neoplasms and 2% of the tumors for which resection is performed. These tumors are also called primary salivary gland-type tumors of the lung because the tracheal and bronchial airway submucosa and the salivary glands contain serous and mucous glands that are histologically similar.¹⁷⁰ Often, they are called bronchial adenomas, but this term is misleading because they are malignant. Care must be taken to separate these primary tumors from metastases of primitive salivary gland tumors.¹⁷¹ This group of carcinomas includes adenoid cystic carcinoma, mucoepidermoid carcinoma, and the even rarer mixed tumor (pleomorphic adenoma). The only truly benign tumors are mucous gland adenomas.

The symptomatology of these tumors is determined essentially by their location and size.¹⁷¹ Peripheral tumors, which are less frequent, are asymptomatic, generally presenting as a nodule on routine chest radiography. Proximally located tumors present with symptoms of bronchial irritation and obstruction, including cough, shortness of breath, hemoptysis, recurrent infection, wheezing, and stridor. Sometimes, patients have constitutional symptoms, such as weight loss and pain. On chest radiography, the nodule may be seen with pneumonia or atelectasis. Because of the slow growth of these tumors, signs and symptoms may develop over a period of years. Incompletely obstructing tumors frequently masquerade as asthma for prolonged periods of time. Smoking does not seem to be a risk factor for these tumors.

Peripheral tumors are diagnosed by percutaneous needle aspiration biopsy or at the time of thoracotomy. Tumors in major airways are diagnosed by bronchoscopy. Other studies, such as CT, are rarely required to make the diagnosis but may

be of value in planning therapy. Because most of these tumors do not metastasize, complete excision, with preservation of as much pulmonary tissue as possible, is the goal. Whenever possible, sleeve resections of main bronchi are performed to preserve pulmonary tissue.

Adenoid Cystic Carcinoma

Adenoid cystic carcinomas are slowly growing malignant tumors that arise from the submucosal glands of the trachea and main bronchi (Fig. 79.8). They have also been called cylindromas, adenoid cystic basal cell carcinomas, adenomyoepitheliomas, and pseudoadenomatous basal cell carcinomas. Adenoid cystic carcinomas behave much like the major and minor salivary gland tumors of the same name, to which they are microscopically identical. An important aspect of their clinical behavior is that they tend to spread in the submucosal plane along the perineural lymphatics, well beyond the obvious endoluminal component of the tumor (Fig. 79.9). In a small biopsy specimen, it can be difficult to distinguish adenoid cystic carcinoma from a conventional adenocarcinoma. Immunohistochemical stains may help the pathologist differentiate the two by showing the presence of the myoepithelial cell immunophenotype in adenoid cystic carcinoma.¹⁷¹

Whenever possible, total excision by tracheal resection or tracheobronchial resection is the treatment of choice.^{172–175} This is not always possible because of the extensive submucosal spread of tumor. In such cases, palliative resection may be necessary. Postoperative radiation is indicated because these tumors are radiation sensitive.

When no resection is feasible because of the extent of the lesion, a palliative treatment option is endoscopic laser removal followed by radiation (brachytherapy, external beam irradiation, or both). When complete resection is possible, the prognosis is excellent. However, because of the slow-growing nature of the tumor and its responsiveness to radiation,

FIGURE 79.8. Tracheogram demonstrating airway obstruction by an adenoid cystic carcinoma of the upper trachea.

FIGURE 79.9. Adenoid cystic carcinoma. A photomicrograph shows perineural infiltration by the tumor. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

prolonged survival is possible even with incomplete resection or palliative measures. Patients frequently live 10 years or more with persistent disease, including pulmonary metastases. In such cases, repeated efforts at palliation are indicated.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas may be of low- or high-grade malignancy and have the same microscopic appearance as mucoepidermoid tumors of salivary gland origin. These tumors also arise in the glandular submucosa, presenting as submucosal lesions. The distinction between low-grade and high-grade tumor is based on mitotic activity, cellular necrosis, and nuclear pleomorphism.¹⁷⁰

The principles of treatment of mucoepidermoid tumors are similar to those of carcinoid tumors. The more malignant variety must be treated as bronchogenic carcinoma. Some authors even think that adenosquamous carcinoma is the same entity as mucoepidermoid carcinoma, but arising in the periphery of the lung.¹⁷⁰ The outlook for these tumors depends on the grade of malignancy and the stage of the disease. High-grade tumors have the same prognosis as bronchogenic carcinoma. Complete resection is the mainstay of treatment. Mucoepidermoid tumors are too rare to permit an evaluation of combined-modality therapy for more aggressive, high-grade tumors.¹⁷⁰

Mucous Gland Adenoma

Mucous gland adenomas are rare submucosal tumors that arise from mucous glands. They are also known as bronchial cysts and papillary cystadenomas. Because of their totally benign behavior, they can usually be treated by endoscopic excision. Thoracotomy and resection are indicated only if the distal lung has been destroyed by chronic infection or if endoscopic removal is technically contraindicated or incomplete.

OTHER MALIGNANT TUMORS OF THE LUNG

The lung is composed of epithelial, mesodermal, and endodermal cells, and malignant tumors may arise from any of these

cells. This group represents fewer than 1% of all primary lung cancers and is usually subdivided into lymphoid tumors, soft tissue sarcomas, mixed epithelial/mesenchymal tumors, and ectopic tissue tumors.^{176,177} Primary pulmonary lymphomas usually are excised for confirmatory diagnosis. Sarcomas arising from soft tissue or large vessels are treated in a similar fashion to sarcomas occurring elsewhere. Treatment of the other rare tumors, including pulmonary blastomas, primary melanomas of the bronchus, and malignant teratomas, primarily involves complete resection. Radiation and chemotherapy do not have well-defined roles in the treatment of any of these tumors but are occasionally used in particular situations.

RESECTION OF PULMONARY METASTASES

Historical Background

The first report of the resection of a pulmonary metastasis performed as a separate procedure is attributed to Divis in 1926. In North America, the most quoted case of lobectomy for a metastatic carcinoma was that performed by Barney and Churchill in 1939.¹⁷⁸ Their patient underwent nephrectomy for an adenocarcinoma and was known to have a pulmonary mass. After the renal resection, the pulmonary tumor did not respond to radiation treatment and increased in size. Following exploration and resection of the pulmonary lesion, the patient survived disease-free for more than 20 years.

From 1940 to the mid-1960s, pulmonary metastasectomy was performed infrequently and only in highly selected patients. A total of 169 pulmonary metastasis resections were performed on 165 patients at the Mayo Clinic from 1941 to 1959.¹⁷⁹ This large number of operations may reflect the high volume of cases seen at the Mayo Clinic rather than the common use of resection at that time. The first principles of pulmonary resection for metastatic disease included complete removal of the primary disease, no evidence of recurrence or metastatic disease other than the lung lesion, and the patient is in good general condition. Multiple lesions were not considered a contraindication to resection (Fig. 79.10), but it was thought that bilateral disease indicated a poor prognosis and should not be resected. Surgeons were already convinced that the resection should be as conservative of lung function as possible.

Since then, experience from several institutions suggests that more liberal indications for pulmonary metastasectomy are appropriate.¹⁸⁰ A striking example was the treatment of metastatic osteogenic sarcoma at Memorial Sloan-Kettering Cancer Center. From 1940 to 1965, only five such patients were treated surgically. During the same period, only 24 of 145 patients (17%) survived 5 years after resection of their primary tumors, and 118 of these patients (81%) died of pulmonary metastases. This experience prompted a more aggressive approach to the management of pulmonary metastases. Starting in 1965, a consecutive series of 22 patients with osteogenic sarcoma underwent pulmonary metastasectomy. Patients were considered for operation even if they had bilateral metastases or required multiple thoracotomies to remove all gross tumor. A total of 59 thoracotomies were performed in these 22 patients, with an overall 5-year survival rate of 32%. The dramatic improvement in survival in comparison with the historical experience strongly supported the aggressive use of pulmonary metastasectomy in these patients.¹⁸¹

During the past 30 years, resection has become a widely accepted treatment for certain pulmonary metastases; however, some of the criteria for patient selection remain controversial. In addition, advances in chemotherapy have changed the indications for resection. With some cancers, pulmonary metastasectomy is performed to prolong life expectancy, whereas with others, it serves mainly to restage disease or to provide adjuvant treatment after initial chemotherapy. The

FIGURE 79.10. Metastatic carcinoma of the lung. A section through the lung shows numerous nodules of metastatic carcinoma, corresponding to “cannon ball” metastases seen radiologically. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

role of pulmonary metastasectomy will undoubtedly continue to evolve as improvements in systemic treatment are made.

Clinical Presentation and Diagnosis

Metastases are asymptomatic 85% of the time and are usually detected on a routine chest radiograph. Patients who undergo resection of a primary tumor with a known tendency to metastasize to the lung should have a chest radiograph as part of their routine follow-up care. On a chest radiograph, metastases usually present as well-circumscribed, spherical solid masses with well-defined borders (Fig. 79.11). Cavitation is occasionally seen in large lesions with central necrosis, mostly squamous cell cancers. The distribution of lung metastases is predominantly subpleural or in the outer third of lung fields.¹⁸²

Metastases to the lung usually arise in the pulmonary parenchyma. Endobronchial metastases are uncommon but occur most typically with renal cell, colon, and breast cancers. Even with endobronchial metastases, half of patients are asymptomatic.¹⁸³ More often, endobronchial disease represents an extension of contiguous parenchymal disease. The extent of endobronchial tumor can affect the approach to resection. For these reasons, bronchoscopy should be performed before thoracotomy, especially if centrally located metastases are present.

Hilar or mediastinal nodal involvement sometimes accompanies pulmonary metastases. Several retrospective series have indicated that metastatic nodal involvement is a poor prognostic indicator, independent of disease-free interval or number of nodules.^{184,185} However, the determinants of nodal involvement and the prognostic and therapeutic implications remain poorly understood. Lymphangitic spread can occur with or without concomitant pulmonary nodules. This happens most frequently in breast cancer and produces a characteristic radiographic

FIGURE 79.11. Chest radiograph of a patient with bilateral pulmonary metastases from endometrial cancer. The mass in the right upper lobe is well circumscribed and has the radiographic appearance typical of a metastasis.

appearance of diffusely increased interstitial markings and a clinical presentation of severe dyspnea that is out of proportion to the radiographic findings.

When pulmonary metastases are thought to be present on a chest radiograph, CT should be performed to determine their number, location, size, and potential resectability. Plain chest radiographs detect only lesions at least 9 mm in size. New lesions of this size seen on a chest radiograph in a patient already treated for a malignancy have a 90% chance of being malignant.¹⁸⁶ Even though CT can identify lesions as small as 3 mm, it often underestimates the number of pulmonary metastases (Fig. 79.12). When radiologic and surgical findings are correlated, only 75% of malignant nodules are detected by CT. Fifteen percent of CT studies overestimate the number of lung metastases for an accurate radiologic assessment of 61%.^{187,188} FDG-PET scan appears to have a role as well in the preoperative evaluation of resectable pulmonary metastases, enhancing the detection of extrathoracic or mediastinal involvement that might preclude complete resection.¹⁸⁹

Patients who present with multiple pulmonary nodules in the setting of a previously treated malignancy rarely pose a diagnostic dilemma. Patients who present with solitary pulmonary nodules are more problematic. Generally, a solitary lesion is more likely to be a metastasis if the primary tumor was a sarcoma or a melanoma. If the primary tumor originated in the head, neck, or breast, it is more likely to be a new primary lung cancer.¹⁹⁰ It has an equal chance of being a metastasis or a new primary tumor if the initial tumor was of gastrointestinal or genitourinary origin. Percutaneous fine-needle aspiration biopsy usually yields a tissue diagnosis, but the necessity of a biopsy in the case of a solitary lesion is questionable. If the patient fits the criteria for resection, a biopsy of the lesion is best performed as an excisional biopsy. Because the findings on needle biopsy do not alter the recommendations for excision of a solitary lesion, this procedure should be undertaken only if the patient is not an operative candidate, if an alternative method of treatment is indicated, or if the patient requests that the diagnosis be established before consenting to operation.

Criteria for Resection

The disease-free interval, number of metastatic nodules, and tumor doubling time all have been used as criteria for the

resection of pulmonary metastases. Each of these remains controversial with respect to its effect on long-term outcome.¹⁹¹ The disease-free interval is defined as the time from resection of the primary tumor to the diagnosis of metastases. The length of the disease-free interval is thought to be of prognostic significance and varies greatly among published reports from 7 months to 5 years.¹⁹²

The number of metastatic nodules resected has also been considered predictive of survival. In sarcomas, some have reported that the presence of four nodules is a significant break-point in survival; however, the significance of the number of nodules varies among reported series. Most consider the completeness of resection the best predictor of survival.¹⁹³ Obviously, when a shower of numerous, tiny (1- to 2-mm) lesions is encountered, complete resection is not possible.

Tumor doubling time is a measure of the aggressiveness of tumor growth. The prognostic importance of tumor doubling time, however, is questioned because various doubling times, from 20 to 136 days, have been found to be significant in different studies.¹⁹² Many do not consider this a criterion for resection. The disease-free interval, number of metastatic nodules, and tumor doubling time in fact reflect the intrinsic tumor biology.

In 1991, the International Registry of Lung Metastases was established. Five thousand two hundred six cases of pulmonary metastases were analyzed retrospectively with regard to prognostic variables.¹⁸⁷ Multivariate analysis showed a better prognosis for patients with germ cell tumors, a disease-free interval of 36 months or more, a single metastasis, and complete resection. A simple system of classification into prognostic groups was designed (Table 79.11).

Several guidelines must be met before a patient is considered for resection of pulmonary metastases: (a) control of the primary tumor, (b) absence of extrathoracic metastases, (c) a general medical condition that permits thoracotomy, (d) pulmonary function that allows complete resection of all metastases, and (e) lack of a more effective systemic treatment. Resection should be undertaken only if complete resection is considered technically feasible.¹⁹⁴

If the metastatic lesion is found at the same time as a recurrence at the primary site, the recurrent primary tumor should be treated before the metastatic disease is treated to prevent further seeding of the metastatic site. When the primary tumor and the metastasis are diagnosed simultaneously, lung resection may precede operation for the primary disease if it is doubtful whether the pulmonary disease can be completely resected and immediate subsequent resection of the primary tumor is planned.

When a patient meets the criteria for resection of one or more pulmonary metastases, the natural history of the tumor and whether effective systemic therapy is available must be considered. Experience in breast cancer, testicular cancer, and osteogenic sarcoma illustrate this point.¹⁹⁵ In contrast to metastatic sarcoma, which is usually confined to the lungs, metastatic breast cancer to the lungs signals the development of widely disseminated disease. Although effective systemic therapy is available, patients with a solitary metastatic lesion, long disease-free interval following treatment for the primary breast cancer, and good performance status appear to have longer median and 5-year survival following pulmonary resection.^{196,197}

The advent of effective chemotherapy has altered the management of pulmonary metastases of germ cell cancer and rendered an incurable disease curable. Platinum-based chemotherapy is now the primary form of treatment.¹⁹⁸ Resection is reserved for patients who have a complete serologic response (normal levels of β -human chorionic gonadotropin and α -fetoprotein) with residual pulmonary lesions, evidence of persistent intrathoracic disease with elevated markers despite a full course of chemotherapy, or lesions that do not respond or that progress with chemotherapy.¹⁹⁹ Approximately one third of the resected pulmonary lesions contain viable tumor,

FIGURE 79.12. Imaging studies from a patient with metastatic embryonal rhabdomyosarcoma. Chest radiographs show a mass in the right lower lobe (arrow, A) that is best seen on the lateral view (arrow, B). Computed tomography (CT) confirmed the presence of this mass (arrow, C) and showed an additional nodule in the left upper lobe (arrow, D). At surgical exploration, however, multiple bilateral pulmonary metastases were found that measured less than 5 mm and therefore could not be seen on CT.

TABLE 79.11 **RESULTS**

SURVIVAL BY PROGNOSTIC GROUP: THE INTERNATIONAL REGISTRY OF LUNG METASTASES

GROUPS		MEDIAN SURVIVAL (mo)
I	Resectable, no risk factor (DFI ≥36 mo and single metastasis)	61
II	Resectable, one risk factor (DFI >36 mo and multiple metastases)	34
III	Resectable, two risk factors (DFI >36 mo and multiple metastases)	24
IV	Unresectable	14

DFI, disease-free interval.

LUNG

one third contain fibrosis or necrosis, and one third are teratomas. A teratoma is removed to prevent it from degenerating to a more malignant form of germ cell tumor and to avoid the potential complications of local tumor growth. Residual tumors are found mostly in patients with positive serology, and the prognosis is usually not as good as when no residual disease is present.²⁰⁰ In addition, the presence of residual pulmonary disease, as opposed to mediastinal disease, appears to portend a worse survival. Patients who are fit for operation can derive significant long-term survival, even though surgical thoracic metastasectomy has a strictly adjuvant role in the treatment of malignant germ cell tumors.²⁰¹

The development of more effective chemotherapy regimens for sarcomas, especially osteogenic sarcomas, has also altered the management of pulmonary metastases in this disease. Resection is part of a multimodality treatment approach, but the manner in which chemotherapy and resection should be combined is less clear than in germ cell cancer. The timing of an operation in relation to chemotherapy depends on the number, size, and location of pulmonary metastases at diagnosis and on whether the patient has received any previous chemotherapy. Often, resection is performed between cycles of chemotherapy, with the aim of controlling both gross and micrometastatic disease. This approach allows the sensitivity of the patient's tumor to chemotherapy to be assessed, and the advisability of continuing the regimen postoperatively can be determined. The thoracic surgeon should collaborate with the medical and radiation oncologists in planning a multidisciplinary treatment program for the patient with pulmonary metastases of sarcoma.

Preoperative Evaluation

The preoperative evaluation of the patient undergoing resection of pulmonary metastases is similar to that of the patient undergoing removal of a primary lung cancer. Tests including pulmonary function, arterial blood gases, and, if necessary, ventilation-perfusion lung scanning are performed to be sure that the patient has sufficient reserve to tolerate complete resection of the metastases. The pulmonary function of patients who received chemotherapy may be substantially reduced. This is particularly true of patients treated with bleomycin and mitomycin, which can markedly diminish the diffusion capacity and, occasionally and unpredictably, cause an acute respiratory distress type of syndrome postoperatively. Maintaining patients on 35% or less inspired oxygen intraoperatively is thought to help prevent this complication. Like patients with primary lung cancers, these patients should stop smoking. Patients who smoke actively up to the time of operation are at risk for postoperative atelectasis or pneumonia.

It is also important to assess the patient's general medical condition and cardiovascular status. Older patients may have underlying coronary artery disease that requires preoperative treatment and additional perioperative monitoring. The cardiac function of patients who previously received chemotherapy, especially doxorubicin, may be impaired. A preoperative radionuclide scan or echocardiogram should be performed to determine the left ventricular ejection fraction and assess whether intraoperative hemodynamic monitoring is necessary. Other drugs, such as cisplatin, can impair renal or neurologic function and may influence perioperative management.

If a patient has recently undergone chemotherapy, the timing of surgery should be planned after consultation with the medical oncologist, so that the operation is not performed when the patient is neutropenic or thrombocytopenic. Resumption of chemotherapy postoperatively should also be a joint decision between the surgeon and medical oncologist so that it does not compromise wound healing.

Surgical Technique

Two principles guide the approach to resecting pulmonary metastatic lesions: complete resection of disease and maximal sparing of functioning lung tissue. Wedge resections should be performed whenever possible. A lobectomy or even a pneumonectomy may be performed when wedge resection will not provide a complete resection. This may be necessary for recurrences (completion pneumonectomy), centrally located tumors, or multiple metastases.^{202,203}

Unilateral disease is approached by a standard anterolateral or posterolateral thoracotomy incision. Patients with bilateral pulmonary metastases should have a simultaneous resection of the bilateral lesions if technically feasible. This can be accomplished by a median sternotomy or a clamshell incision (bilateral anterior thoracotomy with or without transverse sternotomy). A clamshell incision provides better exposure to the posterior aspects of the lungs, particularly the left lower lobe, which is difficult to access by a median sternotomy.²⁰⁴ Bilateral pulmonary nodules may require sequential posterolateral thoracotomies if they are centrally located and good exposure of the hilar vessels is needed.

The role of video-assisted thoracoscopic surgery (VATS) in the management of patients with isolated suspected pulmonary metastasis is clear when performed for diagnostic purposes. VATS wedge resection can be carried out with a high degree of success and minimal morbidity.²⁰⁵ While the use of thoracoscopy in the resection of pulmonary metastases is increasing, its use remains controversial. In a series of 318 patients reported by Petersen et al. undergoing resection of metastatic melanoma, 40 patients underwent thoracoscopic resection.²⁰⁶ According to the authors, thoracoscopy has been their preferred approach to metastasectomy in the past few years; they use chest CT for preoperative localization and ring clamp or digital palpation for intraoperative confirmation.

Gossot et al. compared 31 patients undergoing thoracoscopic resection to 29 patients undergoing thoracotomy for resection of metastatic sarcoma.²⁰⁷ They found no significant difference in 1-, 3-, or 5-year survival. There was also no significant difference in disease-free survival. They recommend a minimally invasive approach for patients with less than two pulmonary nodules that are amenable to wedge resection with no mediastinal or chest wall invasion. Thoracoscopic resection may also be beneficial in terms of causing fewer adhesions, as Briccoli et al. have shown that 35% of patients undergoing metastasectomy for sarcoma will require a repeat resection, resulting in acceptable survival rates as long as pulmonary function is maintained.²⁰⁸

Results

Resection remains the mainstay of treatment for pulmonary metastases from many solid tumors that cannot be treated effectively with chemotherapy. These include melanoma, colon, renal cell, head and neck, and endometrial cancers. The histologic subtypes of the pulmonary metastases in the International Registry of Lung Metastases are listed in Table 79.12.¹⁸⁷

Globally, the actuarial survival after complete metastasectomy is 36% at 5 years and 26% at 10 years (median survival of 35 months).¹⁸⁷ The experience at Memorial Sloan-Kettering Cancer Center in the resection of pulmonary metastases from renal cell carcinoma, head and neck tumors, colorectal cancers, testicular germ cell tumors, and soft tissue sarcoma are summarized (Table 79.13). These results again demonstrate that complete resection of metastatic disease is associated with prolonged survival in carefully selected patients. Furthermore, patients who are persistently free of disease at the primary tumor location but who have recurrent resectable

metastatic disease of the lung also benefit from repeated surgery.²⁰⁹ Mortality rates of pulmonary metastasectomy do not differ from those of thoracic surgery performed for lung cancers, varying between 0.6% and 2%.^{180,199,210} The surgical removal of pulmonary metastases is widely accepted, but its role has changed as more effective chemotherapy has become available for some cancers. It is important that the surgeon understand the indications for operation, the potential side effects of initial chemotherapy, and the ways in which resection should be integrated into the overall treatment plan for these patients.

BENIGN TUMORS OF THE LUNG

Benign tumors of the lung are rare neoplasms. Few series are found in the literature, but in a 10-year surgical review (1958 to 1968) from the Mayo Clinic, 130 patients were found to have benign tumors.²¹¹ Like malignant tumors, benign tumors arising from epithelial, mesodermal, or endodermal cell lines can develop in the lung. They may present as endobronchial lesions but more commonly as peripheral nodules.²¹² Endobronchial tumors present with signs and symptoms related to airway obstruction or bleeding. Tumors arising in peripheral airways or within pulmonary parenchyma usually present as asymptomatic solitary pulmonary nodules. Types of benign lung tumors are listed in Table 79.14.

Hamartoma

The most frequent benign tumors are hamartomas, which represent 75% of benign lesions. They show a predilection for

men.²¹³ A hamartoma consists of an abnormal arrangement of normal cells. In the lung, the most frequent component is cartilage. A hamartoma usually presents as a solitary pulmonary nodule with an extremely slow growth pattern. Classically, the radiographic appearance is that of a well-circumscribed nodule that may contain popcorn calcification. If previous chest radiographs are available, these tumors are found to have been present for many years. Their growth pattern is variable but generally slow. These lesions can be diagnosed by CT if appropriate calcification is demonstrated. Needle aspiration is frequently diagnostic of a cartilaginous benign lesion.

Controversy exists regarding whether these lesions should be excised for pathologic diagnosis. Certainly, they do not require excision unless they are proximally located and cause symptoms related to endobronchial obstruction or unless carcinoma cannot be ruled out. If transthoracic needle aspiration biopsy confirms the presence of a hamartoma, many surgeons elect to follow patients with annual chest radiography rather than surgical excision. Occasionally, significant growth during follow-up necessitates excision.

Other Benign Tumors

Other benign tumors may present as endobronchial lesions (commonly fibromas, lipomas, chondromas, and granular cell myoblastomas). These tumors may be removed endoscopically, but frequently they also require surgical excision when the diagnosis is in doubt or when endoscopic excision has been incomplete. Peripheral tumors often are removed for diagnosis.

CHAPTER 80 ■ CHEST WALL, PLEURA, MEDIASTINUM, AND NONNEOPLASTIC LUNG DISEASE

RISHINDRA M. REDDY

KEY POINTS

- 1 Surgical intervention for chest wall tumors depends on the type of lesion and goals of surgery (resection vs. diagnosis). Reconstruction varies depending on the size of the defect and location on the chest wall.
- 2 Thoracic outlet syndrome may be arterial, venous, or neurogenic. Neurogenic TOS is the most difficult to diagnose, and surgery for this should be performed in high-volume centers.
- 3 The primary treatment for a lung abscess is antibiotic therapy.
- 4 Hemoptysis can be life threatening from suffocation due to a low volume of blood in the lungs, *not* from blood volume loss requiring transfusion.
- 5 Primary spontaneous pneumothoraces will recur in only 30% of patients after initial treatment. When they recur, the treatment should include a thoracoscopic evaluation and possible pleurodesis.
- 6 Transudative pleural effusions should be treated medically, whereas exudative effusions may need more intervention. One quarter of pleural effusions in a community hospital are due to malignancy.
- 7 Empyema is a part of a spectrum of disease that may be treated early on with drainage alone, but may require débridement and decortication in more advanced cases.
- 8 Complications of tracheostomies are usually due to improper placement of the tracheostomy on the trachea (below the third ring, risking a tracheoinnominate fistula) or to the use of high pressures in the cuff of the tracheostomy (causing ischemia and long-term stenosis).
- 9 Mediastinitis is life threatening and warrants immediate evaluation, antibiotic therapy, and surgical drainage.

This chapter is meant as a resource for the general surgery community and general surgery trainees with regard to pathology in the chest. It will cover a wide variety of topics including most noncardiac congenital disease processes in the

thorax. The outline for this chapter is from the Thoracic Surgery Director's Association curriculum for the topics mentioned in the title. The full curriculum can be accessed at www.tsda.org.

FIGURE 80.1. Skeletal support of the thorax. Anterior (A) and lateral (B) views. Note the anterior cartilaginous component of the upper 10 ribs, the fused costal cartilages of ribs 7 through 10, the location of the sternomanubrial junction (angle of Louis) at the level of the second rib, and the oblique course of the ribs laterally from posterior to anterior.

CHEST WALL

Chest Wall Anatomy

The chest wall is the musculoskeletal structure that contains and protects the structures of the upper trunk or thorax. There are two openings to the thorax: the superior aperture, or the thoracic inlet, and the inferior aperture, which leads to the abdominal cavity. The head and arms connect to the intrathoracic structures via the inlet, whereas the diaphragm separates the thoracic and abdominal cavities at the inferior aperture. The inferior vena cava, esophagus, and aorta all travel to the abdomen through the diaphragm at levels T8, T10, and T12, respectively.

The sternum, commonly known as the breast bone, is composed of three parts: the manubrium, the body, and the xiphoid. The manubrium attaches to the clavicles and the first costal cartilages. The sternal angle where the manubrium and body connect is called the angle of Louis and is an important landmark. The second ribs attach to the sternum at this angle, and they allow one to count the ribs from this point down, as the first ribs are not palpable. The body of the sternum contains articular facets for ribs 2 to 7 and connects to the cartilaginous xiphoid inferiorly. The xiphoid may be bifid and will eventually ossify in older adults (Fig. 80.1).

The ribs are split into two groups; the upper seven pairs are the true ribs, with articulations to the sternum, while the lower five pairs are the false ribs. Ribs 8, 9, and 10 connect to each other and the upper ribs via their costal cartilage. Ribs 11 and 12 are called floating ribs as they have no anterior connection. Rib 1 is unique in its shape as it is flat, short, and extremely curved. Ribs 2 through 10 have a more standard configuration with the head containing articular facets for the vertebrae. After the neck the tubercle contains the facet for the vertebral transverse process. The costal groove along the inferior portion of the shaft houses the intercostal bundle, consisting of the nerve, artery, and vein (Fig. 80.2). Because of this inferior placement, most chest wall procedures such as thoracostomy tube placement or thoracentesis should be aimed at the superior aspect of the rib to avoid injury to this bundle.

There are three intercostal muscles: the external intercostal, the internal intercostal, and the innermost intercostal muscle. The intercostal bundle lies just external to the innermost intercostal layer (Fig. 80.3). On the inner aspect of the chest wall, the internal thoracic (mammary) artery and vein runs between the innermost intercostal muscle and the transversus thoracis muscles, which connect the ribs to the lower half of the sternal body. The intercostal arteries have two sources, one posterior and one anterior. The posterior arteries almost all arise from the descending thoracic aorta, while the anterior arteries branch off the internal thoracic artery. The intercostal nerve is a branch off the ventral ramus after it joins the sympathetic trunk. The intercostal veins follow the arteries and posteriorly drain into the azygos and hemiazygos veins. Lymphatic drainage from the posterior chest wall drains into the thoracic duct on the left and into the right lymphatic duct on the right.

FIGURE 80.2. Anatomy of ribs 2 to 10 as viewed from above (A) and below (B).

FIGURE 80.3. Anatomy of the intercostal space. The major intercostal muscles are the external and internal. The neurovascular bundle courses in the costal groove along the inferior aspect of the rib.

The muscles of the chest wall can be divided embryologically into those from the epimeres, such as the deep back muscles, innervated by the dorsal rami, and those from the hypomeres, such as the intercostals and rectus, innervated by the ventral rami. The musculature can also be classified based on respiratory function, where the primary muscles of respiration are the intercostals and the diaphragm, and the secondary, or accessory, muscles are the sternocleidomastoid, scalenes, pectoralis, serratus, and abdominal wall musculature. The major back muscles include the trapezius and latissimus dorsi (Fig. 80.4). In normal breathing, the diaphragm performs most of the work with the intercostals supplying about a quarter of the workload. In full inspiration, the pleura extend bilaterally down to the level of the 11th and 12th ribs (Fig. 80.5).

Chest Wall Neoplasms

Chest wall tumors are very rare. Lesions may be divided into benign and malignant, and then further subdivided into soft tissue versus bony/cartilaginous tumors (Table 80.1). Most malignant tumors of the chest wall are either metastatic from carcinomas or sarcomas arising in other sites of the body, or from local extension of lung cancers or breast cancers.¹

Almost all lesions will present as a mass, as pain, or as a combination of both. Occasionally they will be asymptomatic and be identified on imaging for cancer surveillance or other reasons.² Fever can occasionally be a presenting symptom in the setting of a systemic neoplastic process. Evaluation of these lesions includes a thorough history and physical and appropriate imaging, which may begin with plain radiographs, but should include three-dimensional imaging such as a CT scan and/or MRI. This will allow for evaluation of the depth of the lesion, the relationship of the lesion to nerve and vascular structures, and the pulmonary fields for possible

FIGURE 80.4. Thoracic musculature. Anterior (A) and posterior (B) views.

FIGURE 80.4. (Continued)

B

metastases. Depending on the situation, PET scans may also be useful.¹ Prior films may help ascertain the rate of growth of the lesion.³

Surgical intervention depends on the type of lesion and the goal of surgery. Tumors that are suspected metastases may require only a needle or an incisional biopsy to confirm the

diagnosis. Lesions that are possible primary tumors, whether benign or malignant, require excisional biopsies. Some low-grade malignant tumors may be underdiagnosed and considered benign if the entire specimen is not removed and examined. If a tumor is proven to be a primary malignant lesion, wide excision is required, with margins up to 4 cm.³

FIGURE 80.5. Topographic relations of the pleura to the chest wall. Laterally, the pleura extends to the level of the 11th to 12th ribs. The anterior reflection of the mediastinal and costal pleurae forms the costomediastinal recess, whereas the reflections of the costal and diaphragmatic pleurae form the costodiaphragmatic recess.

TABLE 80.1**CHEST WALL TUMOR CLASSIFICATION**

■ Benign tumors
Soft tissue tumors
Lipomas
Fibromas
Hemangiomas
Neurofibromas
Granulomas
Inflammatory tumor
Tuberculoma
Bony/Cartilagenous tumors
Osteochondromas
Chondromas
Fibrous dysplasia
Eosinophilic granuloma
Osteoid osteomas
Osteomyelitis
Chondro/Osteoblastomas
■ Malignant tumors
Soft tissue tumors
Melanomas and other cutaneous cancers
Sarcomas
Desmoid tumors/low-grade fibrosarcomas
Lymphoma
Malignant fibrous histiocytoma
Bony/Cartilagenous tumors
Chondrosarcomas
Osteogenic sarcomas
Ewing's sarcomas
Solitary plasmocytoma
Lymphoma
■ Metastatic tumors
Breast cancer
Lung cancer
Mediastinal tumors
Mesothelioma
Other sarcomas or carcinomas

Benign Soft Tissue Tumors. These tumors include lipomas, fibromas, hemangiomas, and neurofibromas, among others. These can be removed by excisional biopsy and require no further treatment unless they recur. Inflammatory osteomyelitis can mimic tumors by causing pain.

Benign Bony/Cartilaginous Tumors. About two thirds of benign chest wall tumors are either osteochondromas, chondromas, or fibrous dysplasia, with osteochondromas composing almost 50% of all nonmalignant rib tumors. Osteochondromas usually present as painless masses with a male-to-female predominance of 3:1. If the lesion becomes painful, it may indicate malignant degeneration.³ These tumors are often found on routine radiographic exams for other reasons and have a characteristic appearance of a pedunculated bony prominence (Fig. 80.6).

Chondromas account for 15% of benign rib lesions and grow from the cartilage at the sternocostal junction.¹ They have an equal male-to-female incidence. Clinically and radiographically, it is impossible to distinguish chondromas from chondrosarcomas. It can be difficult microscopically to distinguish chondromas from low-grade chondrosarcomas as well. As a result, all chondromas must be treated as if they are potentially malignant and require complete excision.³

Fibrous dysplasia arises in the lateral portion or shaft of the rib and can have a soap bubble or ground-glass appearance on radiographs (Fig. 80.7). These lesions may become painful if they enlarge and can result in rib fractures. Surgical excision is needed for diagnosis and symptom relief.⁴ Eosinophilic granulomas and

FIGURE 80.6. Osteochondroma of left second rib. The stippled calcification within the tumor and the intact cortex of the rib are characteristic.

osteoid osteomas are rare conditions that affect men more often. Patients may have multiple granulomas, including the skull, and may benefit from radiotherapy as opposed to surgical resection. Osteomas may be symptomatic and if so, should be resected.

Malignant Soft Tissue Tumors. These lesions can range from melanomas to desmoid tumors to malignant fibrous histiocytomas. Sarcomas also arise in the soft tissue of the chest

FIGURE 80.7. Fibrous dysplasia of the rib. Note the characteristic expansion and thinning of the cortex (arrows) and the central ground-glass appearance.

wall, but they compose less than 10% of all sarcomas.² Desmoid tumors are borderline lesions between a benign and malignant classification and are sometimes considered low-grade fibrosarcomas.¹ Almost half of all desmoids occur in the chest wall and shoulder where they can encapsulate the brachial plexus. They require wide local excision and have a high rate of recurrence. If they encircle vital structures, they can be treated with radiotherapy after surgical excision.

Malignant fibrous histiocytoma (MFH) is the most common primary chest wall tumor. These tumors are more frequent in men (2:1 ratio) and generally occur in those older than 50 years of age. They are slow growing, painless, and spread along the fascial planes or between muscle fibers. MFH are unresponsive to other forms of therapy and require wide local excision. Because of the lesion's propensity for fascial plane infiltration, there is a high rate of recurrence following resection, and patients who have undergone resection have a 5-year survival of less than 40%.³ Rhabdomyosarcoma is the second most common soft tissue lesion of the chest wall and usually occurs in children and younger adults. It grows rapidly from the striated muscle but is usually painless. It is treated with wide excision followed by radiation and chemotherapy with a reported 70% survival at 5 years.³ A recent review of soft tissue sarcomas in the chest wall suggested that tumor size greater or less than 5 cm correlates with overall prognosis. Also, patients with low-grade tumors had a 100% 5-year survival rate versus a 69.2% survival in those with high-grade tumors. There was a trend toward improved survival in patients who received a complete resection versus those left with residual disease, but it did not achieve statistical significance due to small sample size.²

Malignant Bony/Cartilagenous Tumors. Chondrosarcomas are the most common primary malignant bony tumors, accounting for 20% to 30% of lesions. These are well-differentiated tumors and on microscopic examination may be difficult to distinguish from their benign counterparts. Local recurrence can occur after excision, and if untreated, distant metastases can develop.³ Osteogenic sarcomas are more common in the limbs but also occur in the ribs. Radiographs depict a characteristic sunburst pattern. These tend to grow quickly and often have metastases at the time of initial presentation. Patient evaluation should include a CT scan and bone scan to check for the presence of metastatic disease. Surgery with adjuvant chemotherapy is the treatment of choice for local disease.⁵ Ewing sarcomas constitute 5% to 10% of chest wall tumors. They occur in children and younger adults with a male-to-female ratio of 1.6:1. Symptoms include pain, fever, and fatigue. Radiographs show a large soft tissue mass with bony destruction. Patients often present with metastatic disease, and ultimately three quarters of patients will develop metastases. Multimodality treatment is the key to treatment. Survival may be less than 30% at 5 years in patients with metastatic disease.⁶

Solitary plasmacytoma is a rare tumor of the plasma cells and can be part of a systemic disease in multiple myeloma. Lesions can be painful and usually occur in men older than 50 years of age. X-ray findings show cortical destruction of the rib (Fig. 80.8). In the setting of systemic disease, only a needle biopsy may be needed, but if the lesion is small and symptomatic, resection can be offered. For larger lesions, radiotherapy is the primary treatment.¹

Metastatic Tumors. As discussed before, metastatic lesions can arise from various other cancers, and treatment depends on the primary histology, time to recurrence, and goals of intervention. For isolated metastases with a long interval before recurrence, surgical resection may be warranted. Each case should be individualized and discussed within a multidisciplinary team.

Chest Wall Reconstruction

Chest wall defects can result from cancer, radiation, trauma, or infection.⁷ The goals of repair are to protect the thoracic

FIGURE 80.8. Plasmacytoma of the left seventh rib, showing characteristic cortical destruction and relatively large soft tissue component projecting into the chest.

1 cavity, minimize complications of respiration due to a flail chest, and to provide cosmetic coverage as needed. Surgical repair involves chest wall stabilization and soft tissue coverage. Stabilization depends on the size and the location of the defect. Often, if the defect is small enough, no stabilization is needed. In larger defects, or when the patient has an intrinsic lung disease limiting the ability to breathe, stabilization using prosthetic materials is warranted. Soft tissue coverage of the defect can vary from mobilization of soft tissue edges, to muscle/omental pedicled flaps, to free muscle flaps.⁸

Size and location generally determine the need for chest wall stabilization. Defects less than 5 cm anywhere in the chest wall or defects less than 10 cm in the posterior chest wall that are anterior to the scapula do not usually need stabilization.^{7,9} An alternative criteria is to use the number of ribs resected, and to avoid stabilization when a portion of three ribs or fewer have been removed.¹⁰ Techniques for closure of the defect include utilizing absorbable Vicryl mesh, used in the setting of infection or if small defects are present. This approach does not provide any stabilization. More definitive repairs use polytetrafluoroethylene (PTFE) or a polypropylene methylmethacrylate (PPM) sandwich mesh. PTFE is a flexible, soft material, whereas the PPM sandwich mesh resembles a hardened piece of plaster between two portions of woven mesh. Different surgeons prefer different approaches, but some of the benefits cited for the PTFE repair include greater stretch and the ability to create a watertight seal.⁷ The PPM sandwich repair, on the other hand, allows the ability to mold the prosthetic and provides a firmer stabilization (Fig. 80.9).⁹ Mortality rates from chest wall reconstruction in the setting of cancer resections have been reported at 4% in multiple series.^{7,9,10}

Flap coverage of the soft tissue defect will almost always require the assistance of a plastic surgeon, and he or she should be involved preoperatively in the planning of a chest wall resection and reconstruction. The decision-making process for which flap to use depends on the location of the defect, the size of the defect, the corresponding size of the flap, and its vascular source. The pectoralis major flap is the most common in the upper chest/neck region. Its blood source can be from the thoracoacromial artery or from intercostal perforators from the internal thoracic arteries (Fig. 80.10). The latissimus dorsi flap is also commonly used for large, ipsilateral defects. Its blood source is from the thoracodorsal artery or from perforators from the posterior intercostal vessels. It has a large arc of rotation from the thoracodorsal pedicle and can cover a wide area of the chest wall (Fig. 80.11). Also commonly used are rectus abdominal muscle flaps in either a vertical (VRAM) or transverse (TRAM) orientation (Fig. 80.12). External obliques can

FIGURE 80.9. Marlex methylmethacrylate sandwich technique for chest wall reconstruction. **A:** Upper anterior chest wall defect resulting from resection of ribs two to five and a portion of sternum. **B:** Marlex methylmethacrylate prosthesis being sutured in place. Heavy, nonabsorbable sutures either encircling the ribs or passed through the sternum are used to anchor the prosthesis in place. **Insert:** Detail of prosthesis showing sandwich of hardened methylmethacrylate between two sheets of Marlex.

FIGURE 80.10. Pectoralis major muscle rotation flap. **A:** Mobilization of the flap by detaching the clavicular, sternal, and chest wall origins as well as the insertion of the muscle on the greater tubercle of the humerus. The dominant blood supply, the thoracoacromial artery, which arises from the axillary artery medial to the proximal border of the pectoralis minor muscle, is shown on the left side where the pectoralis major muscle has been removed. **B:** Medial transposition of the muscle flap, preserving the thoracoacromial neurovascular bundle.

FIGURE 80.11. Latissimus dorsi muscle rotation flap for chest wall reconstruction. **A:** Posterior view showing detachment of the origins of the muscle. The dominant blood supply, the thoracodorsal artery, is preserved. **B:** Anterior view showing the extent to which the mobilized muscle reaches.

be used on the lower anterior chest wall, and the trapezius can be used in the midback.¹¹ Omental flaps are extremely useful and versatile. They can be used to cover large defects or to fill cavities, such as the pleural space in the setting of a bronchopleural fistula and empyema. The omentum can be taken off the right or left gastroepiploic artery, but using the right arterial source allows a greater arc of rotation than from the left. The limitations of this flap are that it requires a laparotomy, although laparoscopic techniques have been described,¹² and that the size of the omentum can be variable and difficult to assess preoperatively (Fig. 80.13).¹¹

Chest Wall Congenital Abnormalities and Thoracic Outlet Syndrome

Pectus Excavatum and Pectus Carinatum. Chest wall deformities occur in 1/1,000 live births. They are five times more common in men than women, and pectus excavatum is five times more common than pectus carinatum. Up to 6% of people with these deformities will also have a connective tissue disorder. Scoliosis is frequently seen in this population.¹³ Pectus excavatum appears as a sternal depression that can be off midline approximately 50% of the time. Pectus carinatum is the opposite, with a sternal protrusion, often described as a “pigeon chest” deformity. Less common deformities include sternal clefts, which are incomplete fusions of the sternum, and Poland syndrome, where there is an absence of a pectoralis muscle and underlying bony support in the chest wall.

Pectus excavatum is the most common of these deformities, and the techniques for surgical correction have been evolving, including the Ravitch and Nuss procedures. Despite this, less than 15% of patients undergo surgery.¹⁴ Most patients present

as children with notable deformities. People can be physiologically asymptomatic but can also present with fatigue, limited stamina, and cardiopulmonary limitations. The workup includes pulmonary function testing, echocardiography, and CT scans. The use of CT scans has been debated in children as the radiation exposure poses a risk. Some advocate that CT scans are needed to show the three-dimensional aspect of the defect and can better reflect the right heart compression. The pectus severity index (Haller index) can be calculated by dividing the inner thorax width by the depth measured from the posterior aspect of the sternum to the anterior aspect of the spine (Fig. 80.14). Normal values are 2 to 2.2, and repair is recommended only when the index is at least greater than 3.1.^{13,15} The age of the patient at which repair should be performed is also somewhat controversial, as some surgeons advocate waiting until after the age of 10 years, but many series have reported on many patients treated at a much younger age with good outcomes.¹⁴ There is a growing experience with treating adults also, as some patients seek repair at a later age (Fig. 80.15).^{16,17}

The most commonly used open repair was first described by Dr. Ravitch and is based on removing sections of the deformed cartilage from around the sternum laterally at the ribs, while preserving the perichondrium. Many advocate using a stabilizing bar for a minimum of 6 months, usually placed in an intrathoracic position, to minimize the occurrence of flail chest and to allow the sternum to heal in an anterior position. An essential part of the procedure is a transverse sternal wedge resection through the anterior table to allow the inferior aspect of sternum to bend forward.^{13,17} Incisions may be in a vertical midline over the lower half of the sternum or in an inframammary position (Fig. 80.16). Recurrences occur in 5% to 10% of patients, with recurrence more common in patients with connective tissue disorders.

FIGURE 80.12. Rectus abdominis muscle rotation flap. Shown is the mobilization of the rectus abdominis muscle, which is based on the superior epigastric artery (the continuation of the internal thoracic artery), and rotation of the muscle and overlying skin to fill an anterior chest wall defect.

Since the 1990s, the Nuss procedure, which uses a minimally invasive approach, has been described and performed. The Nuss procedure uses one or two stabilization bars, secured to the ribs laterally in multiple points of fixation. It routinely employs thoracoscopy, either unilateral or bilateral. Skin incisions are limited to small lateral locations at the site of the bar insertion and thoracoscopic port sites. In both the Ravitch and Nuss procedures, the stabilization bars stay in for at least 6 months.¹⁸ As the Nuss procedure has grown in popularity, many modifications have been made, including precise shaping of the bars and increased bar stabilization with wire fixation around the ribs to minimize bar displacement.¹⁹

Pectus carinatum doesn't have the same cardiac compression concerns as pectus excavatum, but the chest is held in an enlarged position, limiting normal respiration mechanics. Patients can have increased residual lung volumes, and their respiratory physiology can mimic emphysema physiology. This can result in breathing difficulties and limited stamina.¹⁷ The Ravitch procedure is most commonly performed to remove the deformed cartilage. Special attention is placed on the transverse sternal osteotomy, to depress the sternum and align it with the anterior ribs (Fig. 80.17).¹³

Sternal Clefts. Sternal clefts are much rarer than either pectus deformity. They result from the failure of the sternum to fuse in the midline. They can vary from minor defects with the

FIGURE 80.13. The omentum can be used to cover large defects. Shown is an open sternal wound after débridement with failed prior muscle flap (A). Wound 6 months after omental flap placement (B). (Reproduced with permission from Ghazi B, Carlson G, Losken A. Use of the greater omentum for reconstruction of infected sternotomy wounds: a prognostic indicator. *Ann Plast Surg* 2008;60(2):169–173.)

upper half of the sternum separated, to complete dissociation and thoracic ectopia cordis (the heart being outside the chest wall). Upper sternal defects have a U- or V-shaped appearance and usually extend to the fourth intercostal space (Fig. 80.18). Repair of these defects can be easily performed by incision, complete sternotomy, oblique chondrotomies of the sternal halves, and closure. Complete sternal clefts are associated with diastasis recti and an opening between the peritoneal and pericardial cavities. Inferior clefts are associated with the pentalogy of Cantrell, a constellation of defects that include: supraumbilical abdominal wall defect, lower sternal cleft, defect in the anterior diaphragm, defect in the associated pericardium, and congenital cardiac defects, often tetralogy of Fallot. With the increased use of prenatal ultrasound, most cases are diagnosed early and are being appropriately referred to specialists prior to birth.²⁰

Poland Syndrome. Poland syndrome is the clinical absence of a pectoralis muscle and underlying bony support in the chest wall, and it occurs in 1/30,000 live births. It is usually a right-sided, unilateral defect. Patients commonly have associated limb abnormalities and may also present with renal and spinal lesions (Fig. 80.19). Clinical symptoms may be absent, though lung herniation can occur, requiring a more urgent repair. The surgical approach is usually multidisciplinary and ideally is deferred until after the patient has stopped growing. Repairs

typically use mesh placement over the defect, and/or muscle flap placement.²¹

Thoracic Outlet Syndrome (TOS). The thoracic outlet in TOS refers to the area described at the beginning of this chapter as the thoracic inlet, the correct anatomic term for the region of the first rib and the middle and anterior scalene muscles. Through these structures, the brachial plexus, subclavian artery, and subclavian vein travel to the upper limbs (Fig. 80.20). Because of the close proximity in this area, these

conduits may be subjected to abnormal compression by inflammation around the muscles or abnormal bony structures such as cervical ribs, causing pain, thrombosis, and other symptoms that are described as TOS. TOS can be divided into arterial, venous, or neurogenic diseases, or a combination, depending on the symptoms and clinical findings. Vascular TOS is easier to document with vascular imaging. Neurogenic TOS is more difficult to diagnose. Unfortunately for neurogenic TOS, there is no gold standard diagnostic test to confirm the syndrome. As a result there has been significant controversy over the diagno-

FIGURE 80.18. Cleft sternum at rest (A) and during forced expiration (B). Superior clefts of the sternum are variously V- or U-shaped. The appearance of the child as he cries explains the term *ectopia cordis*, although the heart is actually not misplaced. In the newborn, defects of this kind can be corrected by direct apposition of the sternal halves. In this child, closure of the defect was made possible by sliding chondrotomies on either side. (Reproduced with permission from Sabiston DC Jr. The surgical management of congenital bifid sternum with a partial ectopia cordis. *J Thorac Surg* 1958;35:118.)

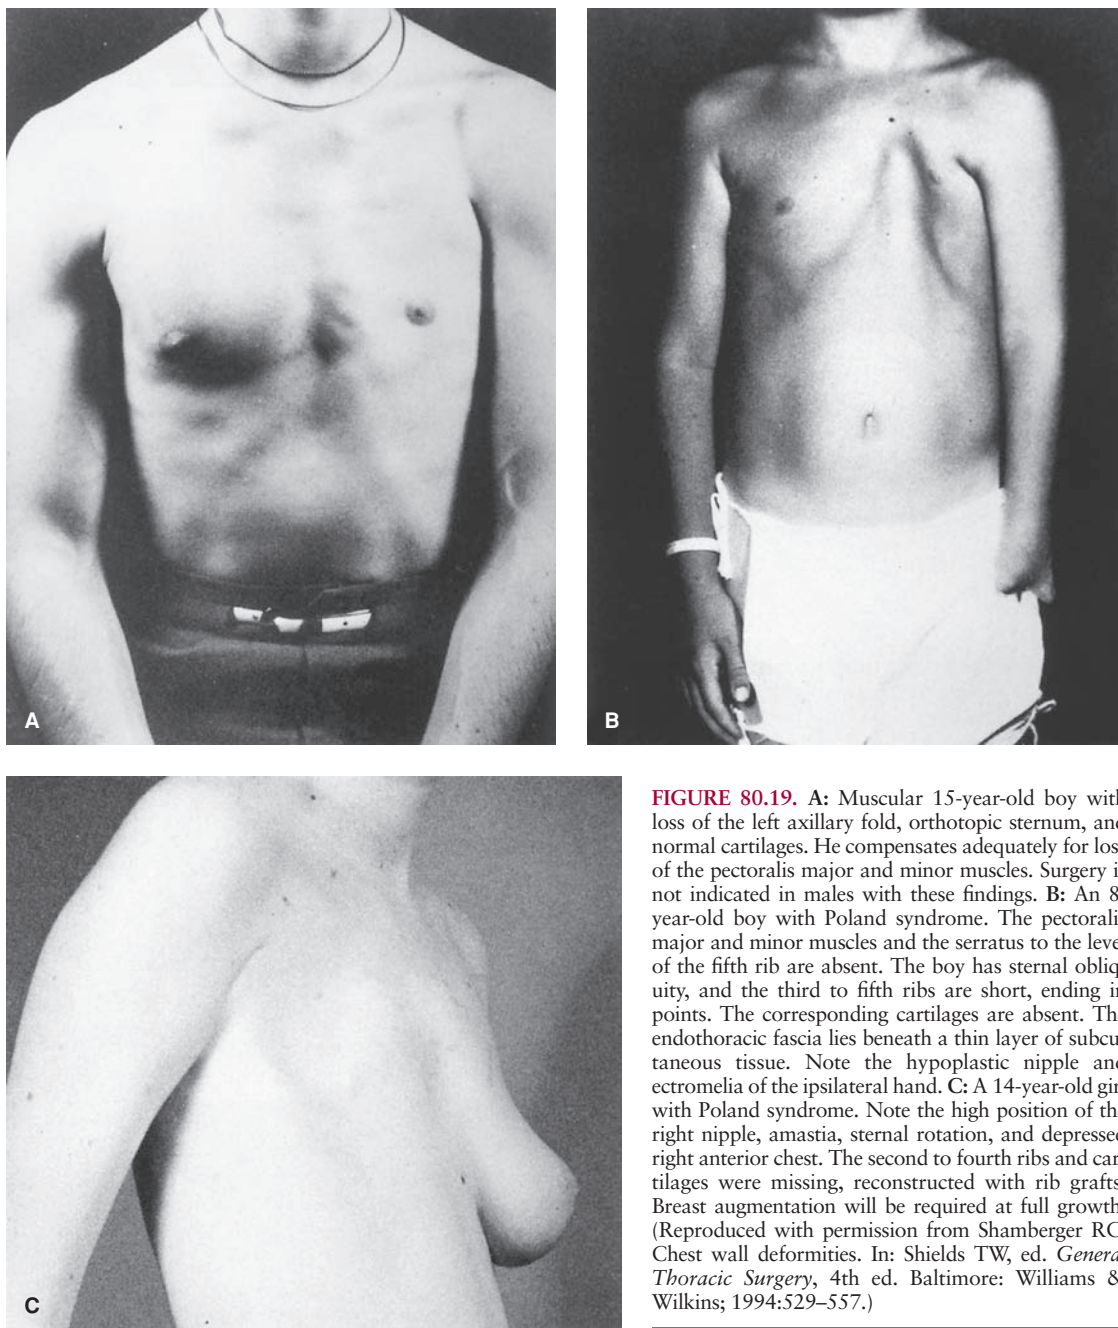

FIGURE 80.19. A: Muscular 15-year-old boy with loss of the left axillary fold, orthotopic sternum, and normal cartilages. He compensates adequately for loss of the pectoralis major and minor muscles. Surgery is not indicated in males with these findings. B: An 8-year-old boy with Poland syndrome. The pectoralis major and minor muscles and the serratus to the level of the fifth rib are absent. The boy has sternal obliquity, and the third to fifth ribs are short, ending in points. The corresponding cartilages are absent. The endothoracic fascia lies beneath a thin layer of subcutaneous tissue. Note the hypoplastic nipple and ectromelia of the ipsilateral hand. C: A 14-year-old girl with Poland syndrome. Note the high position of the right nipple, amastia, sternal rotation, and depressed right anterior chest. The second to fourth ribs and cartilages were missing, reconstructed with rib grafts. Breast augmentation will be required at full growth. (Reproduced with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*, 4th ed. Baltimore: Williams & Wilkins; 1994:529–557.)

sis and the indications for surgical treatment, especially in light of the potential for significant postoperative complications.^{22,23}

Vascular TOS can be divided into venous disease and arterial disease. Venous disease results in thrombosis of the subclavian vein and is also called Paget-Schroetter syndrome. This syndrome usually presents in men who use their upper bodies and dominant arm for work. Symptoms may present as pain, swelling, and cyanotic discoloration.²² Contrast venography is the best test to make the diagnosis, and the radiologist should be instructed to perform positional maneuvers with the patient's arm to replicate narrowing that occurs with arm movement.²³ Arterial TOS accounts for about 5% of all cases of TOS²⁴ and also may result from repetitive and strenuous use. Patients will present with arm fatigue and may even have evidence of ischemia in their distal digits. Patient evaluation includes pulse exam with the arm relaxed and elevated, bruit exam for poststenotic dilatation, and blood pressure readings in both arms. Duplex scanning and angiography will often con-

firm the diagnosis. Decompression of the scalene muscles and any abnormal bony structures will alleviate these symptoms.²²

Neurogenic TOS presents with limb pain, numbness, or weakness. Symptoms may be bilateral, but are usually worse in the dominant arm. The distribution may not follow a peripheral nerve pattern, thus making the diagnosis confusing, but also ruling out more distal compression syndromes such as carpal tunnel in the wrist or cubital compression at the elbow. The physical exam should be focused on duplicating the patient's symptoms. The Adson maneuver may detect artery compression and is performed by palpating the affected radial pulse and having the patient take a deep inspiration while turning the head away from the affected arm (Fig. 80.21). The test is positive if the pulse disappears, but a positive result can also be seen in asymptomatic people without TOS. Another test requires the patient to elevate the arms in a "surrender" position and open and close their hands repeatedly. Most people with neurogenic TOS will be fatigued within a minute and be

ORIENTATION

unable to continue (Fig. 80.22). Plain radiographs may show bony abnormalities, but no other imaging will help diagnose neurogenic TOS. Physical rehabilitation is the first step to treat patients with neurogenic TOS, and over a third of patients may get a significant improvement in their symptoms. If there is no significant improvement in symptoms, then surgical intervention is suggested.²³

The surgical approach for TOS was traditionally a transaxillary first-rib resection (Fig. 80.23). In recent years, a supra-

FIGURE 80.21. The Adson maneuver. Patient inspires and turns head away from the affected arm. The test is positive if the pulse disappears.

FIGURE 80.22. Surrender position with opening and closing of hand. Early fatigue is seen in neurogenic TOS.

clavicular approach has become increasingly popular as it gives better exposure to the scalene muscles and any cervical ribs. In either approach, the first rib is exposed and the anterior and middle scalene muscles are removed from their attachments to the rib. Once this is performed, the first rib is removed (Fig. 80.24). Special attention must be paid to the phrenic nerve laying along the anterior scalene and the axillary branches off the brachial plexus. Small drains may be placed in the apex of the thorax if the pleural space is entered.^{23,25} The supraclavicular approach also gives access to perform a cervical sympathectomy if indicated for symptoms consistent with sympathetic overactivity. In patients with arterial aneurysms, reconstruction with synthetic grafts or autologous conduits such as an external iliac artery can be performed. For patients with venous TOS, care should be taken to perform a circumferential venolysis and to remove the medial aspect of the first rib.²⁵

Postoperative complications include pneumothorax, lymphatic leaks (especially on the left side where the thoracic duct enters the operative field), phrenic nerve palsy, and traction injury to the brachial plexus.²⁴ Patients should have good pain control and may need muscle relaxants to minimize muscle spasm. There should be limited restrictions to the operated extremity to maximize movement and minimize the risk of developing a frozen shoulder. Rehabilitation should be restarted as soon as possible after surgery.^{23,25} Up to 12.5% of patients may not get any symptom relief after the surgery, and long-term physical rehabilitation is recommended.²⁴ Patients with combined symptoms of venous and neurogenic TOS have worse outcomes when compared to patients with only venous disease. A higher percentage of patients had persistent pain in the neurogenic group as might be expected.²⁶ The treatment of this disease process requires a significant investment into the preoperative and postoperative care of these patients and should be done only in centers with a high volume and expertise in this syndrome.

NONNEOPLASTIC LUNG DISEASE

Lung Abscess and Bronchiectasis

Complications from pulmonary infections that require surgery are not common relative to the frequency of pneumonias in

FIGURE 80.23. Position of the patient and skin incision for transaxillary approach. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:Fig. 29-1.)

both the inpatient and outpatient community. However, in some patients, treatment of lung abscesses and bronchiectasis may include surgical intervention. Lung abscesses can result from aspiration or occur after necrotizing pneumonia. Patients may present with chest pain and fever. Routine use of antibiotics for pneumonias has dramatically reduced the rate of lung abscess sequelae. In more than 80% of cases, a pathogen can be found, and in immunocompromised patients, there are usually multiple organisms involved including *Pseudomonas aeruginosa* and *Haemophilus* species. The primary treatment for lung abscesses is medical with antibiotics. If a patient is clinically not improving with medical therapy alone, a guided drainage tube may be placed. A complication of this approach

is the risk of a chronic air leak from a percutaneous tube placed into the lung parenchyma. Surgery may be indicated in the setting of large abscesses causing hemoptysis or other symptoms (Algorithm 80.1). Surgical resection may also be of clinical benefit in some patients by removing lung tissue damaged by necrotizing pneumonia.²⁷

Bronchiectasis is the abnormal dilation of bronchi/bronchioles as the result of multiple episodes of infection and inflammation. Factors contributing to the development of this disease may be genetic, anatomic, or even systemic. Genetic causes include cystic fibrosis, which results in diminished mucus clearance and diffuse bronchiectasis in both lungs.²⁸ Primary ciliary dyskinesia is an autosomal recessive syndrome resulting in

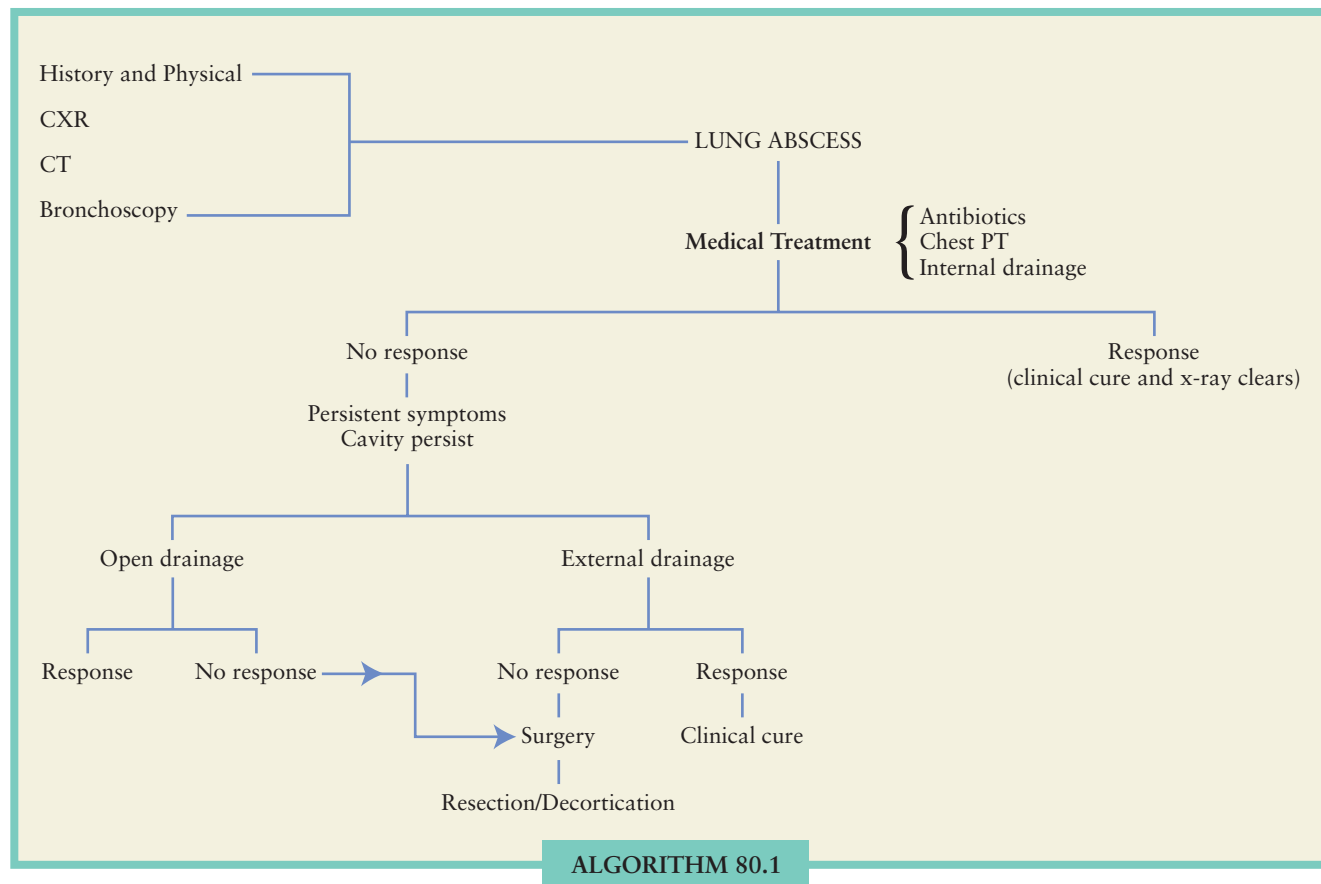

FIGURE 80.24. Division of the scalene muscles and the first rib. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:Fig. 29-2.)

abnormal cilia that cannot clear secretions leading to multiple infections. Individuals with alpha1-antitrypsin deficiency can also develop bronchiectasis. Anatomic causes include postsurgical changes or acquired diseases such as chronic obstructive pulmonary disease (COPD) that lead to an increased risk of infection, again by the inability to clear secretions. Autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease have been associated with increased rates of bronchiectasis.^{28,29} Infectious causes include allergic bronchopulmonary aspergillosis and nontuberculous *Mycobacterium* infections. Reflux disease is also being studied as a potential contributor. Most often the etiology of the disease is idiopathic.²⁸

There are estimated to be 110,000 patients in the United States being treated for non-cystic fibrosis bronchiectasis each year. The diagnosis is increasingly being made as a result of an increasing number of chest CT scans being performed for other nonrelated reasons. Patients can present with respiratory symptoms such as dyspnea, hemoptysis, or pleuritic pain, or alternatively may present only with systemic changes such as fatigue and weight loss.²⁸ Almost all patients will have a

chronic cough with or without sputum production.²⁹ Pulmonary function tests may demonstrate moderate to severe airflow obstruction.²⁸ A chest CT scan is the optimal test to diagnose bronchiectasis (Fig. 80.25), and once the diagnosis is made, the search for an etiology should begin, including obtaining sputum cultures and blood tests for autoimmune markers such as rheumatoid factor.²⁹

The treatment of the disease includes antibiotic therapy to control infection, the treatment of underlying diseases if they exist, reducing inflammation, improving secretion clearance, and surgery to remove focally damaged areas or transplantation if needed for more diffuse, severe disease. Antibiotic therapy includes inhaled tobramycin and gentamicin.²⁹ Macrolide antibiotics have been increasingly studied for their nonantibiotic effects. Erythromycin and clarithromycin have anti-inflammatory benefits. They disrupt the biofilm produced in *Pseudomonas* infections resulting in decreased sputum volume and improved symptoms.³⁰ Secretion removal is also essential to improving symptoms. Besides the standard treatments of percussive therapy and postural drainage, the use of nebulized

ALGORITHM 80.1. Algorithm for management of lung abscess. (Adapted from Shields TW, ed. *General Thoracic Surgery*, 6th ed. 2005: Fig. 86-7.)

acetylcysteine²⁹ or hypertonic saline³⁰ have been shown to improve mucus clearance.

Surgical intervention may occur at many stages of the disease process. Bronchoscopy can be useful to clear secretions or to manage hemoptysis. If the bronchiectasis is localized to a single lobe, resection can eliminate the disease and the source of chronic infection. If a patient has a genetic disease such as cystic fibrosis, a double lung transplant may be the best treatment if the patient's symptoms are severe enough.²⁹ Pulmonary tuberculosis can have similar indications for surgical intervention when it results in bronchiectasis or hemoptysis.³¹ The rise of more multi-drug-resistant tuberculosis strains has led to the increasing need for surgical intervention.³²

Hemoptysis

4 Hemoptysis is often used to describe any blood streaking associated with cough. True hemoptysis may be only a few drops of blood, and it requires investigation. Massive hemoptysis is acutely life threatening, not from blood or volume loss, but rather from suffocation secondary to blood in the airway. The immediate goals when this is encountered are airway control, improved oxygenation, and resuscitation if needed. Intubation may or may not be necessary, depending on the volume of blood in the airway and the patient's ability to cough.³³ If the bleed is able to be lateralized, the patient should be placed

ALGORITHM 80.2. Hemoptysis management. (Adapted from Jean-Baptiste E. *Crit Care Med* 2000;28(5):1642–1647.)

in a lateral decubitus position with the bleeding side in the dependant position. The causes of hemoptysis include cancer, infections/bronchiectasis, vascular injuries, vasculitides, and coagulopathies.³⁴

In patients with hemoptysis, any coagulopathy should be corrected. Early bronchoscopy is essential, and the goals are to lateralize the side of bleeding and identify the site and cause of the bleeding. Flexible bronchoscopy may be done, but rigid bronchoscopy is the best approach to maintain airway control, in particular in the setting of large-volume hemoptysis. Initial treatment may include topical therapy such as cold saline lavage, bronchial tamponade, and intubation of the contralateral good lung. Double lumen endotracheal tubes may also be useful to isolate and protect the uninvolved lung from blood from the contralateral side obstructing its lumen.³³ If a patient is stable, a chest CT scan is useful to identify tumors or other potential sources of bleeding.³⁴

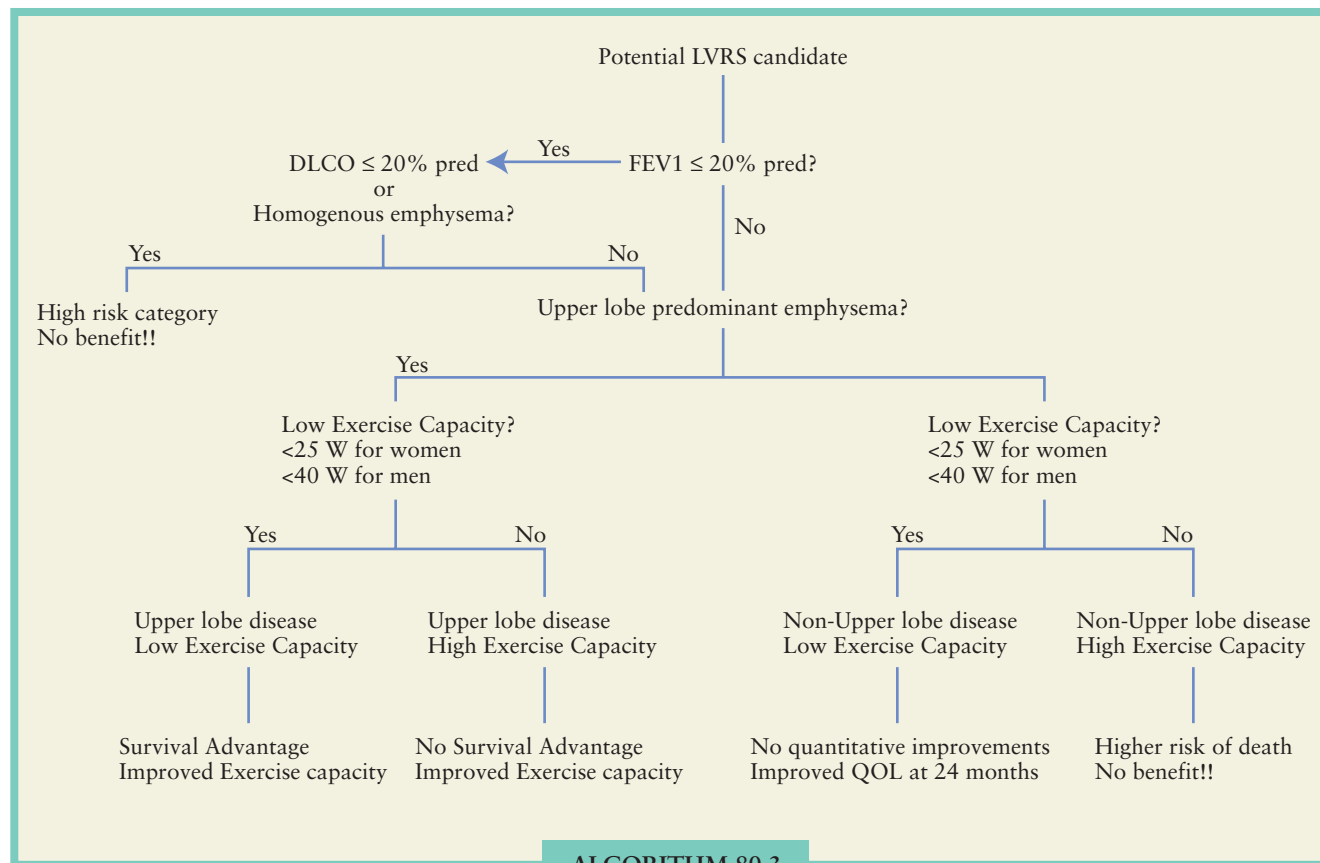

Once a patient is stabilized and appropriate diagnostic tests performed, the treatment of continued bleeding includes the use of interventional radiology and bronchial artery embolization (BAE).³⁵ First introduced in 1973, BAE is the best nonsurgical treatment of massive hemoptysis, with a success rate of up to 98% within 24 hours.³⁴ Surgery is reserved to treat the underlying condition once the patient has been stabilized and bleeding controlled by other methods. Emergent surgery to treat bleeding may have a mortality rate as high as 38%³⁵ and increase to 59% in the setting of malignancy.³⁴ Depending on the patient's baseline lung function, a lobectomy, let alone a pneumonectomy, may not be tolerated. A risk assessment of the benefits of surgery must be performed. In the setting of a vascular etiology of the hemoptysis such as a ruptured aortic aneurysm, surgical repair is essential and should not be delayed

once the patient is hemodynamically stable and the airway is controlled.³⁴ A detailed algorithm in the assessment and treatment of hemoptysis is shown in Algorithm 80.2.

COPD and Lung-Volume Reduction

Chronic obstructive pulmonary disease (COPD) includes a broad group of diseases that result in airflow obstruction and hyperinflation. Medical therapy involves smoking cessation, bronchodilator treatment, steroids, home oxygen, and antibiotics as needed. Despite improvements in the medical management of this condition, patients continue to suffer severe limitations due to their breathing and exercise capacity. As a result, surgical interventions have continued to play a role in trying to ameliorate symptoms and improving survival in these patients.^{36,37}

There is a more than 50-year history in the literature recording various surgical approaches to help treat COPD. Interest has diminished, however, because of the high mortality associated with surgical intervention in this patient population. In the 1990s, a renewed interest in lung-volume reduction surgery (LVRS) was observed following reports that this procedure was associated with a low published mortality rate and a significant improvement in forced expiratory volume in 1 s (FEV1) seen on pulmonary function testing. There was a national increase in interest in the procedure, as many centers began offering it. Despite continued publication of low mortality rates, evaluation of Medicare data in 1996 showed a mortality of 23% in surgically treated patients at 12 months, and Medicare reimbursement for the procedure stopped. This led to the development of the National Emphysema Treatment

ALGORITHM 80.3. LVRS candidate workup. (Adapted from Martinez FJ, Chang A. *Semin Respir Crit Care Med* 2005;26(2):167–191.)

Trial (NETT), a prospective randomized trial to evaluate the outcomes of lung-volume reduction surgery compared to optimal medical treatment.³⁶

The goal of the NETT study was to evaluate short- and long-term survival, lung function, exercise capacity, and quality of life. Centers used both median sternotomy and bilateral video-assisted thoracoscopic surgery (VATS) approaches to perform the operative procedure. Interim analysis identified a high-risk subgroup with a higher mortality. These patients had low FEV1 (less than 20% predicted) and either a homogenous pattern of emphysema in both upper and lower lungs or a low carbon monoxide diffusing capacity (DLCO) (less than 20% predicted). The mortality at 30 days was 16%, and the risk was felt to be prohibitive. As the study continued, two preoperative factors appeared to be associated with decreased mortality: dominant upper-lobe emphysema and having a higher preoperative exercise capacity. Using these factors, patients were divided into four subgroups. Patients with upper-lobe disease and a low exercise capacity, defined as achieving less than the 40th percentile on exercise testing, 25 Watts for women and 40 Watts for men, showed a survival advantage and improved exercise capacity after surgery. Patients with upper-lobe disease and high exercise capacity, achieving more than the 40th percentile cutoff, showed no survival advantage but did have improved long-term exercise capacity. Patients with non-upper-lobe disease and low exercise capacity had no survival or exercise improvements but did note an improved quality of life at 24 months. The remaining patients with non-upper-lobe disease and high exercise capacity had a higher risk of death and no significant improvement in exercise capacity or quality of life. The 30-day mortality in the non-high-risk subgroup was 5.5%. Long-term follow-up

showed the same results in all subgroups except in the non-upper-lobe disease and low exercise capacity group. The quality of life improvement had disappeared by 3 years (Algorithm 80.3).³⁶ This subgroup analysis has allowed surgeons to better counsel patients as to the benefits of LVRS, based on which group they fall in.

When the different surgical approaches were evaluated, there was no difference in mortality or benefit from sternotomy versus video-assisted thoracoscopic (VATS) approaches. Sternotomy patients had a longer hospital stay and higher costs noted at 6 months. The cost effectiveness of LVRS was also evaluated. The mean cost for LVRS was much higher at 1 year than for the medical therapy group, \$71,515 versus \$23,371, respectively.³⁸ In the subgroup with upper-lobe disease and low exercise capacity, at 2 years of follow-up, there was a cost of \$98,000 per quality-adjusted life-year (QALY). This was predicted to fall to \$21,000 at 10 years. In comparison, coronary artery bypass graft surgery has a cost of \$64,000 per QALY.^{38,39}

A new technique aimed to provide the same benefit of LVRS but without the surgical risk is the placement of one-way endobronchial valves. These are designed to allow air to escape the hyperinflated apical regions and not allow air to re-enter. Endobronchial stents have been designed to cross bronchioles into hyperinflated regions of the lung and allow decompression. Other approaches being tested include the bronchoscopic introduction of biologic substances such as trypsin or thrombin into hyperinflated regions of the lung with the goal of causing local scarring and reduce the hyperinflation.³⁸ Other surgical procedures in the treatment of COPD include bullectomy in selected patients and lung transplants in patients with end-stage disease.³⁷

Tracheobronchial Foreign Body (TFB) Aspiration

TFB aspiration occurs most often in children, but up to 20% of cases have been reported in adults. Risk factors in adults include older age, as elderly patients have a higher incidence of neurologic disease and an impaired cough reflex. Symptoms usually involve an episode of choking, followed by a protracted cough. Fever, dyspnea, and wheezing can also be present.⁴⁰ Chest x-ray view may aid in the diagnosis if the aspirated TFB is radiopaque or if there is associated air trapping, atelectasis, or pneumonia; however, the TFB is visible less than a quarter of the time as most foods are not radiopaque.⁴¹ Chest CT scans are a more sensitive imaging modality but not necessarily more specific. Bronchoscopy should be performed if TFB aspiration is suspected. Removal of the TFB can usually be accomplished by flexible bronchoscopy but may require rigid bronchoscopy in difficult cases.^{40,41}

Pneumothorax

Pneumothoraces are classified as spontaneous, primary or secondary, traumatic, or iatrogenic. Primary spontaneous pneumothoraces occur in patients with no known lung disease, whereas secondary spontaneous ones occur in patients with underlying lung pathology thought to predispose those patients to a pneumothorax. Iatrogenic pneumothoraces may occur in either the postsurgical or postprocedural setting, typically following central line placement or thoracentesis.⁴² Traumatic pneumothoraces are covered elsewhere in this text.

- 5 Primary spontaneous pneumothoraces occur more frequently in men than in women, with an incidence of 7 to 18 cases per 100,000 people for men, compared to an incidence rate of 1 to 6 cases per 100,000 people in women. Most cases occur in males younger than 30 years of age, and they rarely occur in people older than the age of 40 years. Even though many patients with primary pneumothoraces do not have apparent lung disease, almost all are found to have subpleural bullae, the pathophysiology of which is unknown.⁴² Most bullae are

apical in location.⁴³ Patient symptoms can range from minimal to severe and usually include pleuritic pain, dyspnea, or both. Tachycardia may also be present, and if a person is tachycardic and hypotensive, a tension pneumothorax must be high on the differential and appropriate needle decompression considered. A tension pneumothorax occurs when air entering the pleural cavity cannot escape and the air compresses the vena cava and even the heart, resulting in hemodynamic instability (Fig. 80.26). Urgent needle decompression followed by chest tube placement is the preferred treatment. Most spontaneous pneumothoraces occur while patients are at rest.^{42,44}

Observation is often the treatment of a stable, small pneumothorax, defined as being less than 3 cm from the apex. For a larger pneumothorax, chest tube placement is the standard treatment, though some advocate a trial of aspiration. Most patients will have a complete resolution of their pneumothorax and not need further treatment. In the group of patients who have a persistent air leak from the initial pneumothorax, or the 30% who have a recurrent pneumothorax, usually within 2 years, further treatment is warranted. This involves some form of pleurodesis, chemical or mechanical, either via a chest tube (talc infusion), or during a thoracoscopic evaluation where apparent blebs can also be resected (Algorithm 80.4).^{43,44}

Secondary spontaneous pneumothoraces can occur due to various lung diseases, but COPD is the most common.⁴⁵ Although primary pneumothoraces can be mild clinical events, secondary ones are much more concerning because of the baseline lung disease and poor pulmonary reserve. Observation has no role in this patient population, who should undergo definitive treatment to prevent a recurrence during the first event. Here a thoracoscopic approach may be more effective in establishing an adequate pleurodesis and allow the evaluation for sources of air leaks.⁴⁴ Iatrogenic pneumothoraces can result from transthoracic needle lung biopsies, central line placement, thoracentesis, transbronchial lung biopsies, pleural biopsies, and positive-pressure ventilation. Patients with underlying lung disease are at a higher risk of developing a pneumothorax after these procedures. Treatment should follow the same paradigm as for spontaneous pneumothoraces. Patients with a small, asymptomatic, stable pneumothorax and no underlying lung

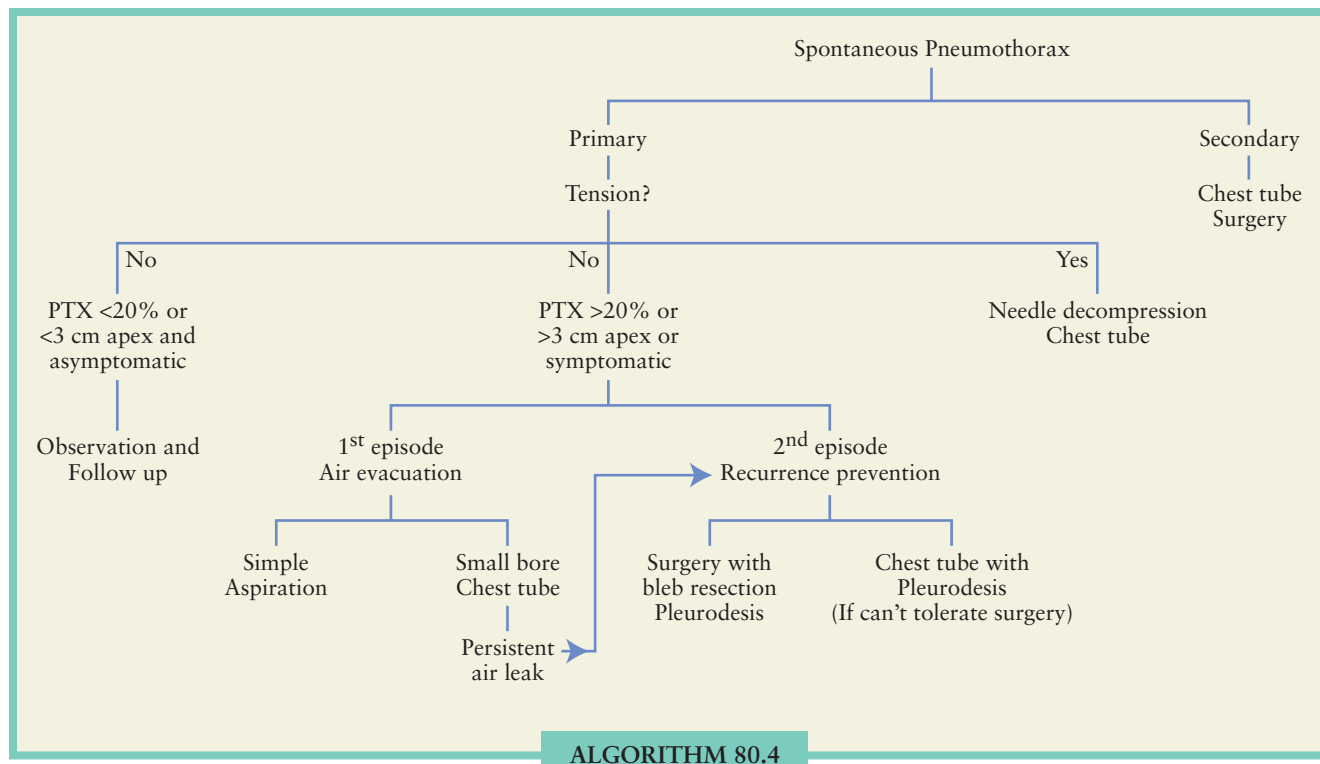

FIGURE 80.26. A: A 40% left-sided spontaneous pneumothorax (arrow). B: Progression of simple pneumothorax to a tension pneumothorax, showing the characteristic radiographic findings—virtual collapse of the entire involved lung, shift of the mediastinum to the contralateral side, and compression of the contralateral lung. Subcutaneous air dissecting along the left chest wall is also evident.

ALGORITHM 80.4. Algorithm to treat pneumothorax. (Adapted from Baumann MH, Noppen M. *Respirology* 2004;9(2):157–164.)

disease may be safely observed, although all others should undergo placement of a chest tube.⁴⁴ Some studies have suggested immediate aspiration of air after a CT-guided lung biopsy resulting in a pneumothorax, with an 85% success rate in avoiding the need for chest tube placement.⁴³

Congenital Lung Disease

Congenital malformations of the lung develop during fetal lung growth. They may be identified during an in utero evaluation, present as respiratory distress in the newborn, or be completely asymptomatic and found in patients as adults. They can frequently occur with other congenital malformations and may be life threatening. Lung development begins during week 3 from the foregut. It progresses through birth to approximately 2 years of age when alveolar development is complete. The five stages of lung development have been divided into the embryonic, pseudoglandular, acinar, sacular, and alveolar stages (Table 80.2). Malformations may occur at each step and lead to different pathologic conditions.⁴⁶ Four separate conditions will be discussed here; pulmonary seques-

tration, lobar emphysema, congenital cystic adenomatoid malformation (CCAM), and bronchogenic cysts.⁴⁷

Pulmonary Sequestrations. Pulmonary sequestrations are defined as pieces of parenchymal lung separated from the respiratory tree, with the sequestration receiving its blood supply from an anomalous artery arising from the aorta rather than having the blood supply arising from the pulmonary artery. Sequestrations have been further subdivided into extralobar and intralobar lesions, with very distinct anatomic alterations and clinical presentations. Extralobar sequestrations reside outside of the true pleural space. Venous drainage is usually into the azygos or hemiazygos veins. They are most often on the left side between the left lower lobe and diaphragm (Fig. 80.27). Up to 80% of extralobar sequestrations occur in males. Most patients present with dyspnea in the first 6 months of life. They may be diagnosed by fetal ultrasound or after birth by chest x-ray view. Other congenital abnormalities are found in up to two thirds of patients, with congenital diaphragmatic hernias present in a quarter of patients.⁴⁶ Intralobar lesions reside within the normal lung and within the normal pleura. They are almost always in the lower lobes and occur in the left side just over 50% of the

TABLE 80.2

PHASES OF LUNG DEVELOPMENT CLASSIFICATION

■ PHASE	■ GESTATION PERIOD	■ MAJOR DEVELOPMENTS
Embryonic	26 days to 6 weeks	5 lobar bronchi
Pseudoglandular	6 weeks to 16 weeks	Cartilage rings, cilia form
Acinar/Canalicular	16 weeks to 28 weeks	Type I and II pneumonocytes
Saccular	28 weeks to 34 weeks	Distal airspace development
Alveolar	34 weeks to 2 years	Alveoli proliferate from 20 to 600 million

FIGURE 80.27. A: Abnormal radiograph of the chest of a newborn with respiratory distress (A). Ultrasound identified the anomalous vessel coursing through the diaphragm and entering the sequestration (B). This computed tomographic scan clearly demonstrates the anomalous artery arising from the thoracic aorta and entering the sequestered lung (C). (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*, 6th ed. 2005:Fig. 80-15.)

time. Venous drainage is usually through the pulmonary vein. It is suggested that intralobar sequestration may be an acquired disease, caused by repeated episodes of inflammation that lead to bronchiole narrowing and scarring. Ultimately the “lobe” becomes isolated and may develop new feeding blood vessels from collateral arteries in the inferior pulmonary ligament. A complete assessment of a sequestered lesion must be performed prior to resection and should include assessment of any potential airway or gut connection, determining the vascular supply of the sequestration, and determining if there are any other congenital malformations.⁴⁶

Congenital Lobar Emphysema. Lobar emphysema is the cause of half of the episodes of newborn respiratory distress that are due to structural anomalies. Two thirds of the cases occur in males. Distention of the distal lung occurs from obstruction of the airway, either from an intrinsic cause, such as meconium or torsion, or an extrinsic cause, such as obstructing lymph nodes. In up to half of the cases, no cause can be found. Almost all cases occur in the upper lobes, with almost equal distribution between sides. Half of the lesions will present in newborns, and the remaining 50% will reveal themselves by 6 months. Chest x-ray studies are diagnostic (Fig. 80.28).⁴⁶ Surgical resection may not be immediately necessary and may be delayed until the child has grown or until he or she develops a failure to thrive. Even after surgical resection, patients may have bronchomalacia and a tendency toward bronchospasm.⁴⁸

Congenital Cystic Adenomatoid Malformation. CCAM lesions are the second most common cause (25%) of newborn respiratory distress, secondary to structural problems. Children will present either at birth or in early childhood

with recurrent respiratory infections. The anomalies are due to an overgrowth of bronchioles, likely during the acinar phase of fetal lung development. Lesions can occur on either side and usually are isolated to one lower lobe. The classification system by Stocker (Table 80.3) organizes these lesions based on pathologic

FIGURE 80.28. Radiograph of a newborn with lobar emphysema involving the right middle lobe. Note the compressed right lower lobe and mediastinal shift. (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*, 6th ed. 2005:Fig. 80-6.)

TABLE 80.3**THE STOCKER CLASSIFICATION OF CCAM**

appearance and clinical outcome. Prenatal MRI best serves to evaluate these lesions, whereas postnatal chest x-ray view and/or chest CT scan can be used to differentiate CCAMs from other lesions.⁴⁶ Even though lesions may be small and asymptomatic, these lesions possess the potential for malignant transformation and should be resected (Fig. 80.29).⁴⁸

Bronchogenic Cysts. Bronchogenic cysts are formed from primitive foregut tissue present in the airway. They can present as single or multiple cysts in a wide variety of locations in the thorax. They usually present in young children who develop symptoms such as stridor due to airway obstruction or compression caused by the cysts.⁴⁷ Alternatively, cysts located within the lung parenchyma can become infected and present as an abscess. Therapeutic aspiration may be temporizing, but ultimately surgery is needed.⁴⁹ Resection may have a mortality of up to 14%, but untreated lesions have a 100% mortality.⁴⁷

FIGURE 80.29. Specimen removed from an infant with a cystic adenomatoid malformation. Microscopically, there was marked proliferation of terminal bronchioles, and cartilage was lacking (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*, 6th ed. 2005:Fig. 80-24.)

Most cases of congenital lung disease will present in the first 6 months of life. The main symptom is usually respiratory distress, but once children reach 1 year in age, chronic infections become the most common symptom. Diagnostic tests begin with chest x-ray views but can include ultrasound, MRI, CT scans, angiography, and bronchoscopy, depending on the lesion and location.⁵⁰ Decision making regarding the timing of surgical resection should incorporate the patient's acuity due to symptoms and his or her overall ability to tolerate surgery based on size.

PLEURAL DISEASE

Pleural diseases include benign complications from systemic disease, postoperative infections, local infections, and cancers from primary and metastatic sites. Diseases involving the pleura can lead to limitations to respiration and symptoms of dyspnea. Surgical intervention may be indicated, and it is imperative for the surgeon to be able to recognize which disease processes require a surgical procedure. Pneumothoraces are discussed earlier in this chapter, and here we will cover pleural effusions, including empyemas and malignant pleural mesotheliomas.

Pleural Effusions

Pleural effusions are a common condition that elicit a surgical consult for potential drainage and even thorascopic intervention to assist in the diagnosis and treatment of the condition. The essential first step in the evaluation of a new effusion is to determine if it is a transudative or exudative process. A transudative fluid collection is the result of a poorly balanced hydrostatic and/or osmotic pressure across the pleural membrane resulting in increased serum leak across the pleural barrier. Exudative processes result from inflammation or neoplastic processes that cause increased capillary leak at the pleural membrane. Because of the leaky membrane, larger proteins can enter the pleural fluid resulting in higher protein and lactate dehydrogenase (LDH) levels in the exudative fluid compared to the transudative fluid (Table 80.4).⁵¹ One of the tests used most often to make the diagnosis is the Light criteria, where the serum and pleural fluid protein and LDH levels are measured (Table 80.5). If one or more of the criteria are met, then the fluid is considered exudative.⁵² Other tests have been evaluated, including measuring cholesterol ratios and the albumin gradient, but the Light criteria is still the best overall test.⁵¹

Transudative effusions are most often caused by congestive heart failure. Even if a patient has no other symptoms of heart failure, in the setting of a transudative effusion, a complete cardiac workup should be considered. Other causes include cirrhosis, which may or may not be associated with ascites. Isolated right- and left-sided effusions due to liver disease have been described. Effusions can be seen in more than 20% of patients with nephrotic syndrome, and so all patients with new effusions should be evaluated for the presence of proteinuria. Rarer causes include retroperitoneal urine leaks or cerebrospinal fluid leaks.⁵²

- 6 Surgical interventions, such as chest tube placement, should be avoided in these disease settings, as patients will continue to drain fluid from their chest until the primary cause is treated. Aspiration of fluid may help temporarily while systemic treatment is instituted but should only be done as part of a larger treatment plan.

Exudative effusions have several etiologies, but malignancy is the number one cause.⁵² Approximately a quarter of pleural effusions in a community hospital setting have been attributed to cancer. The malignancies that cause the effusions are, in order of decreasing frequency, lung cancer, breast cancer, and hematologic cancers such as lymphoma. Other malignancies, such as ovarian cancer, can also cause effusions.⁵³ The next most

TABLE 80.4**DIAGNOSIS****DIFFERENTIAL DIAGNOSIS OF PLEURAL EFFUSIONS**

Transudative pleural effusions	Collagen vascular diseases
Congestive heart failure	Rheumatoid pleuritis
Pericardial disease	Systemic lupus erythematosus
Cirrhosis	Drug-induced lupus erythematosus
Nephrotic syndrome	Immunoblastic lymphadenopathy
Peritoneal dialysis	Sjögren syndrome
Superior vena cava obstruction	Wegener granulomatosis
Myxedema	Churg-Strauss syndrome
Pulmonary emboli	Postcardiac injury syndrome
Sarcoidosis	Asbestos exposure
Urinothorax	Sarcoidosis
EXUDATIVE PLEURAL EFFUSIONS	Uremia
Neoplastic diseases	Meigs syndrome
Metastatic disease	Yellow nail syndrome
Mesothelioma	Drug-induced pleural disease
Infectious diseases	Nitrofurantoin
Bacterial infections	Dantrolene
Tuberculosis	Methysergide
Fungal infections	Bromocriptine
Viral infections	Procarbazine
Parasitic infections	Amiodarone
Pulmonary embolization	Trapped lung
Gastrointestinal disease	Radiotherapy
Esophageal perforation	Electric burns
Pancreatic disease	Urinary tract obstruction
Intra-abdominal abscess	Iatrogenic injury
Diaphragmatic hernia	Ovarian hyperstimulation syndrome
Postabdominal surgery	Chylothorax
Endoscopic variceal sclerotherapy	Hemothorax

common causes of exudative effusions are infections, including pneumonias causing parapneumonic effusions, tuberculosis (TB), and fungal infections. Although rarer in the United States, TB is still a common etiology worldwide. If someone is suspected of having pleural TB, the pleural fluid should be evaluated for adenosine deaminase (ADA) and gamma-interferon levels, which if low will rule out the diagnosis of TB. If other infections are suspected, the pleural fluid should be cultured. Pancreatitis may also cause an exudate, and elevated serum amylase levels will support the diagnosis. Autoimmune processes, such as rheumatoid disease and lupus, can also cause effusions. Chylothorax presents after problems with thoracic duct lymph

drainage in the chest lead to an accumulation of lymphatic fluid in one or both thoraces. The thoracic duct collects lymph from the cisterna chyli, the plexus of lymphatics in the upper abdomen, and travels anterior to the spine and just posterolateral to the aorta. It follows behind the aorta and enters the left neck where it empties into the confluence of the left internal jugular and subclavian veins (Fig. 80.30). Chylous leaks are due primarily to thoracic duct injury from trauma, surgery, or lymphomas resulting in obstructed lymphatics. Pleural triglyceride and cholesterol levels will be elevated, and the fluid will have a milky color. Treatment for persistent chylothoraces include thoracic duct ligation by surgery or by embolization of the site of leak in the interventional suite.⁵²

The management of malignant pleural effusions includes various options, but critical to the decision-making process is the knowledge of the median life expectancy in that patient due to the underlying malignancy. Chest tube drainage may be therapeutic and diagnostic, allowing fluid drainage and alleviation of symptoms of dyspnea. It will also allow determination of whether the underlying lung is able to expand. If not, it is described as a “trapped lung” and although the fluid may be gone, a persistent pneumothorax appears on chest x-ray views as the lung cannot expand and fill the thorax. In these settings, an indwelling pleural drainage catheter may be the best option to intermittently drain accumulating fluid. Decortication is not recommended, as most patients with malignancy in this setting have a limited life expectancy and the success rate is low

TABLE 80.5**CRITERIA FOR EXUDATIVE EFFUSIONS BASED ON RATIO OF PLEURAL FLUID PROTEIN AND LDH CONCENTRATIONS TO SERUM CONCENTRATION**

Protein/serum protein >0.5
LDH/serum LDH >0.6

compared to decortication in the setting of an empyema. VATS exploration may also be used to remove loculated fluid collections and to evaluate for lung re-expansion after the procedure. If the lung re-expands, further treatment includes pleurodesis, using talc, doxycycline, or bleomycin. These medications will cause an inflammatory reaction between the parietal and visceral pleura resulting in the lung being “stuck” in an expanded state. Mechanical pleurodesis can also be performed by mechanical débridement of the pleura via VATS. Chemical pleurodesis may be performed via VATS or through an existing thoracostomy tube. The goal of treatment in the setting of a malignant pleural effusion is palliation.⁵³

7 Empyema. Empyemas are defined as frank pus in the thoracic cavity. This represents part of the continuum of disease that begins with simple parapneumonic effusion, where exudative fluid is not infected and not loculated. As the disease progresses, fluid becomes loculated with fibrinous septations and becomes infected, leading to pus and ultimately the development of a fibrinous peel. Up to half of pneumonias have an associated effusion, but less than 5% of cases lead to an empyema.⁵⁴ Other causes include surgical thoracotomies and/or other infections from nearby organs, such as esophageal injuries. Pleural infections have been categorized into three overlapping stages. The first is the exudative stage, where the fluid is thin, sterile, has a lower white blood cell (WBC) count and LDH levels, and the glucose level is still greater than 40 mg/dL (Table 80.6). Treatment usually involves addressing the underlying etiology, such as a pneumonia. The second stage is the fibrinopurulent stage, where the fluid becomes infected and fibrin deposits accumulate on the pleura. The LDH and WBC count increase, and the glucose and pH levels drop. The fluid becomes thick and purulent, and the lung is often unable to expand. Chest tube drainage alone at this stage may not be effective to remove the fluid. The third stage is the organizing stage, and a thick pleural peel is created by migrating fibroblasts. At this point, a formal débridement and decortication is required to allow the lung to return to full function.⁵⁴

Organisms causing empyemas have shifted from predominantly *S. pneumoniae* in the preantibiotic era, to anaerobic organisms in up to three quarters of empyemas in the current era. Imaging to evaluate the presence of an empyema begins with a simple chest x-ray view but requires a chest CT to show potential loculations. After the institution of antibiotic therapy, surgical intervention depends on the stage of the disease but may require a VATS exploration or even a thoracotomy to débride the thorax effectively and to decorticate the pleural peel off the lung to allow re-expansion.⁵⁴ Postpneumonectomy empyemas are an especially difficult problem as there is no lung tissue to occupy the empty thorax. Risk factors in this setting include right pneumonectomies (vs. left), the need for postoperative ventilation, lower starting hemotocrit levels, and poor preoperative pulmonary function test results.^{55,56} Treatments of these empyemas are particularly difficult and may include an Eloesser flap or the Clagett procedure, which allow for the creation of an open wound that permits packing and granulation tissue to form in the empyema cavity.⁵⁷

Mesothelioma. Malignant pleural mesothelioma (MPM) is a cancer of the serosal pleura, related to the exposure to asbestos. Multiple hypotheses have been formed regarding how asbestos causes mesothelioma and include the idea that asbestos fibers are inhaled deeply into the lung and penetrate the parenchymal surface, causing irritation of the pleura and repeated episodes of inflammation, ultimately leading to cancer. Other potential mechanisms include asbestos interfering with mitosis, inducing free-radical production, and induction of proto-oncogene kinases by asbestos fibers.⁵⁸ Exposure to asbestos usually occurs decades prior to presentation with mesothelioma and has been seen in miners exposed to asbestos dust, industrial workers such as plumbers and carpenters who used asbestos products, and even in 20% of patients with no

TABLE 80.6

DIAGNOSTIC CRITERIA FOR PLEURAL FLUID IN EMPYEMA

■ STAGE	■ FLUID/PEEL	■ WBC	■ LDH (cells/mm ³)	■ pH (IU)	■ BACTERIA
Exudative	Thin/elastic	<1000	<500	>7.3	Absent

known exposure but living in industrial countries. Mesothelioma is a relatively rare malignancy, with less than 5,000 cases in the United States per year.⁵⁹

Patients with mesothelioma may present with dyspnea or chest pain. Often, patients are asymptomatic and the diagnosis is made after abnormalities are seen on a chest x-ray view performed for another reason. Radiographs may show unilateral effusions and a loss of volume on the affected side, as the lung capacity is diminished due to disease. As the disease progresses, patients may have weight loss, worsening pain, and night sweats. Median survival may be as little as 1 year from the time of diagnosis.⁶⁰ Diagnostic studies include a chest CT scan or MRI to show the extent of pleural thickening (Fig. 80.31). Lymphadenopathy or signs of local spread through the diaphragm or chest wall can also be seen with three-dimensional imaging. The pathologic diagnosis almost always requires a tissue biopsy. Cytologic examination of pleural fluid from a thoracentesis cannot differentiate between mesothelioma cells and other potential lung cancers. CT-guided biopsy of pleural thickening can often give the diagnosis, but ultimately a VATS approach or limited thoracotomy may be needed to obtain a diagnosis. If the patient is being considered for surgical resection, a limited thoracotomy in the site of a potential later incision is optimal to limit seeding of the tumor.⁶⁰

Mesotheliomas can be categorized into epithelial, sarcomatoid, and mixed histologies. Patients with epithelial histology do better than those with a sarcomatoid histology.⁶⁰ There are various staging systems for mesothelioma, including the Butchart system, the revised Brigham and Women's Hospital system, and the TNM-based system by the International Mesothelioma Interest Group (IMIG) (Table 80.7).^{60,61} The IMIG system allows for better reproducibility of the interpretation of local and regional lymph node spread. Laparoscopy may be useful to evaluate the patient for transdiaphragmatic spread of the tumor, differentiating between T3 and T4 tumors.⁶¹

Treatment for mesothelioma may include chemotherapy, radiation therapy, and surgery. Surgical treatment ranges from a pleurodesis for palliation in the setting of effusions and unresectable disease, to pleurectomy/decortication for limited dis-

ease, and to the most aggressive treatment of an extrapleural pneumonectomy (EPP), with the goal of complete tumor resection. Less than a third of patients are candidates for any surgical intervention. Preoperative workup for an EPP should include a cardiac evaluation, and optimal surgical candidates have pulmonary function tests with an FEV1 of greater than 2 L/s and an age younger than 70 years.⁶¹ Surgery involves an en bloc removal of the lung, pleura, pericardium, and diaphragm with reconstruction of the pericardium and diaphragm. Pleurectomy and decortication is reserved for very early-stage disease and involves removal of the pleura only with preservation of the lung parenchyma. Multimodality approaches have shown better results, with neoadjuvant chemotherapy and adjuvant radiation therapy.⁶² Chemotherapy for advanced disease includes pemetrexed and cisplatin or the combination of gemcitabine and cisplatin. Both have shown similar levels of palliation. Radiotherapy may also be used but is limited by the large field requiring treatment and the risks of pneumonitis and esophagitis.⁵⁸ It is best used in combination with EPP for local control after surgery or to treat local painful areas.⁶¹ Because of the few cases per year, most patients who are considered for surgery should be referred to high-volume centers where surgeons and other clinicians are comfortable treating this disease.

TRACHEA

The trachea is a well-known structure to general surgeons who may perform tracheostomies and bronchoscopies as part of their clinical practice. A thorough knowledge of the anatomy and vascular supply is essential to minimize complications such as postintubation tracheal stenosis and tracheoinnominate fistulas after tracheostomies.

Anatomy

The trachea is the connection from the cricoid cartilage to the carina that allows ventilation and mucous clearance from the lungs. It is oval, with C-shaped cartilaginous rings creating the anterior and lateral borders. A soft tissue membrane forms the posterior wall to complete the oval shape. In the average male, the anterior-posterior dimension is 1.8 cm, whereas the lateral aspect is 2.3 cm. Tracheal length reaches almost 12 cm with almost two rings per centimeter. Trachea in women are 10% to 20% smaller. In children, the shape is more circular, but becomes gradually more ovoid as they age. There is a significant amount of flexibility in the normal trachea, and remodeling can occur in chronic disease states such as emphysema. The inner lining consists of ciliated pseudostratified columnar epithelium with goblet and mucous cells interspersed. At the carina, the right and left mainstem bronchi split off. The right side is characterized by the quick take-off of the right upper lobe bronchus, with the bronchus intermedius continuing into the middle- and lower-lobe bronchi. The left side has a longer mainstem bronchus with a split into the upper and lower lobes.⁶³ The blood supply begins with the inferior thyroid artery supplying the cervical trachea through three tracheoesophageal branches. The lower trachea is supplied by bronchial arteries arising off the aorta. As the arteries approach the trachea, they further split to supply separate segments. Even within segments, they will branch into anterior and posterior transverse intercartilaginous arteries (Fig. 80.32). Because of this segmental blood supply, there should be minimal circumferential dissection around the trachea to limit impairment of the blood supply and healing in tracheal/bronchial surgery.

Surgical Airways

The most common tracheal procedure is a tracheostomy. Over the last 20 years, there has been an increasing use of percutaneous

tracheostomy. For patients who are intubated, the indication for and timing of tracheostomy depends on a multitude of factors, of which there is very little consensus in the medical literature. The goal of a tracheostomy is to limit the risk of laryngeal stenosis caused by prolonged endotracheal intubation, to improve pulmonary toilet, and to improve oral hygiene. Generally, tracheostomy should be considered after a patient has been intubated for more than 7 days, without clear expectation for immediate extubation.⁶⁴ Ideally, patients should be on minimal ventilator settings, but tracheostomy may be performed in patients with elevated oxygen (FiO_2 of up to 60%) and ventilatory (positive end-expiratory pressure [PEEP] less than 10) requirements. Patients requiring more support are at high risk of decompensating if they lose their airways, even if just for a moment, and the decision to perform a tracheostomy should be carefully considered in this setting.⁶⁵

Tracheostomies are performed with the neck extended. A 2- to 3-cm incision is made approximately 2 cm above the sternal notch. Dissection is carried down through the platysma, and the strap muscles are divided longitudinally. Exposure of the trachea and the second and third rings may require elevation of the thyroid. Lateral traction sutures may be placed around the second or third rings. A vertical incision is made between rings two and four and gradually dilated. A tracheostomy tube is placed under direct vision.^{64,66} Percutaneous tracheostomy placement is based on the Seldinger technique. A needle is placed percutaneously into the trachea at the estimated level of the second or third rings with bronchoscopic visualization. A guidewire is placed into the airway and serial dilations performed, until a tracheostomy tube is able to be advanced over the wire.⁶⁵ Cricothyroidotomy should be performed only in the emergent setting. The cricothyroid membrane is palpated below the superior thyroid notch. A transverse incision is made to the lateral borders of the thyroid cartilage. Rapid dilation is followed by tube insertion.⁶⁴

8 Complications can vary depending on the technique. For open tracheostomy, they include damage to the carotid artery, internal jugular vein, posterior tracheal wall/anterior esophagus, and apex of the lung.⁶⁵ Also reported are fires due to the use of electrocautery in the setting of nitrous oxide and oxygen.⁶⁴ In percutaneous tracheostomies, complications include pneumothorax, mediastinal emphysema, paratracheal insertion, tracheoesophageal fistula, and airway loss.^{65,67} Common complications include local hemorrhage and infection. Major late complications include tracheal stenosis and tracheoinnominate fistulas. Fistulas result from erosion of the tracheostomy

tube into the innominate artery. Improper placement of the tracheostomy into rings lower than the third ring place patients at higher risk for this complication. A sentinel bleed may be the initial presentation. Pressure on the fistula with immediate repair or ligation of the vessel is required (Fig. 80.33).⁶⁸ Postintubation stenosis is usually due to necrosis caused by high-pressure cuffs resulting in impaired blood flow to the segmental area of the trachea. This leads to the long-term loss of cartilage and narrowing of the airway. The use of low-pressure cuffs has reduced the incidence of this complication but not eliminated it. Bronchoscopy and dilation may alleviate symptoms, but resection of the stenotic area may be needed (Fig. 80.34).⁶⁶

Tracheal Tumors

Benign lesions of the trachea are less common than malignant ones. They include papillomas, chondromas, hamartomas, fibromas, and hemangiomas. Papillomas are associated with the human papilloma virus and can degenerate into malignant lesions, thus requiring resection. Chondromas arise from the cartilage and may recur after resection. Hamartomas are composed of cartilage and epithelial and lymphatic tissue. Recurrence is rare after resection. Fibromas can be resected via bronchoscopy. Hemangiomas are the most common pediatric tracheal mass. They may regress without treatment and can be observed if not causing obstructive symptoms. Biopsy is generally avoided due to bleeding risk. Surgery may be required if lesions persist.⁶⁹

Although more common than benign lesions, malignant tracheal tumors are very rare with only 600 to 700 cases in the United States per year. Lesions may be primary tracheal lesions, tumors from adjacent organs growing into the trachea, or metastatic lesions.⁷⁰ Primary tumors are most commonly squamous cell carcinomas or adenoid cystic carcinomas in the trachea, followed by carcinoids in the bronchi.^{70,71} Adjacent tumors may arise in the lung, esophagus, thyroid, or mediastinum. The most common cancers that cause tracheal metastases include renal cell cancers, sarcomas, breast cancers, and colon cancers.⁷⁰ Patients will present with stridor and wheezing and have often been recently diagnosed with adult-onset asthma and treated with inhalers and even steroids without alleviation of symptoms. Hemoptysis may also occur, though it is more common in lung cancer than in tracheal disease.⁷¹ Patients should undergo imaging such as a neck and chest CT scan to assist in making the proper diagnosis. Bronchoscopy with a flexible or rigid endoscope is essential to aid in the evaluation of the extent of disease and to control the airway if necessary. Treatment includes tracheal resection for primary tumors if possible. For metastatic disease, palliative treatment includes endoluminal resection and/or radiotherapy.⁷¹ Endoluminal treatments include mechanical core out, YAG-laser treatment, photodynamic therapy (PDT), cryotherapy, or brachytherapy. Stenting also may play a role to maintain airway patency, either for a temporary period during radiation treatment or in the setting of end-stage disease (Algorithm 80.5).⁷⁰

Tracheomalacia and Airway Stents

Tracheomalacia occurs when the trachea loses its rigid form and the posterior membranous wall approaches the anterior wall, causing luminal narrowing and obstruction leading to dyspnea. Patients have a characteristic seal-like cough. Chest CT scans may demonstrate this condition, and pulmonary function testing in these patients will show reduced FEV1, forced vital capacity (FVC), and peak expiratory flow rates. Bronchoscopy is the best diagnostic test and reveals real-time airway collapse with expiration. Etiologies include congenital tracheomalacia, extrinsic compression, postintubation stenosis and inflammation, relapsing polychondritis, and chronic obstructive pulmonary disease.⁷² Surgical intervention may

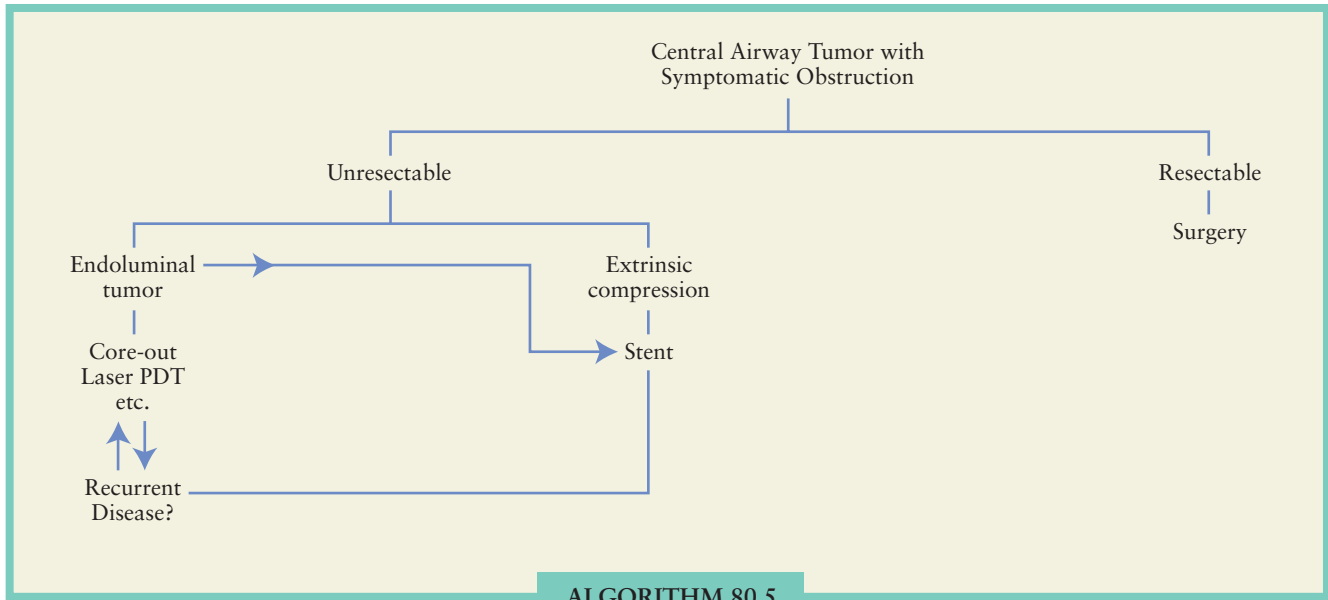

FIGURE 80.33. Management of tracheoinnominate artery fistula. **A:** Common mechanism of injury from erosion of innominate artery by adjacent tracheostomy tube. **B:** Emergency treatment of hemorrhage involves insertion of an endotracheal tube into the tracheostomy stoma, inflation of the cuff, and downward and outward pressure on the fistula by the finger inserted through the tracheostomy incision to further tamponade the bleeding. **C:** Through a partial upper sternal split, the segment of involved innominate artery is resected and the oversewn ends covered with adjacent mediastinal fat or muscle. Tracheal resection is usually not necessary. A new tracheostomy tube may have to be inserted higher in the trachea or, if possible, the tracheostomy tube removed and the stoma covered with a sternohyoid muscle flap.

include resection for localized involvement, tracheoplasty, or stenting.^{72,73} Airway stents can be divided into two groups, silicone and metal, with each type having distinct advantages (Table 80.8). Silicone stents require rigid bronchoscopy to place, have a narrower inner lumen, and are more easily displaced. Advantages to the use of silicone stents are that they are easily adjustable or removable, they do not develop tissue ingrowth, and they are nonreactive to the endoluminal lining. Metal stents can be placed by flexible bronchoscopy and conform to the trachea better. They are permanent and difficult to adjust. Placement requires fluoroscopy, and granulation tissue often grows in between metal struts making subsequent

removal difficult.⁷⁰ Newer stents being developed include covered metal stents that prevent tumor ingrowth along the stent, but unfortunately still allow granulation tissue to grow in at the ends.⁷⁴ In addition to being useful in the setting of tracheal stenosis, they can also play an essential role in palliating post-transplant bronchial stenosis.⁷⁵

MEDIASTINUM

The mediastinum contains several important structures and may be involved in different disease processes. Mediastinal

ALGORITHM 80.5. Algorithm for management of tracheal masses. (Adapted from Wood DE. *Surg Clin North Am* 2002;82(3):621–642).

infections are not as common as they were in the past, but when they present, they are life-threatening situations. The mediastinum is divided into several compartments, including the superior, anterior, middle, and posterior regions. Sometimes the lower three compartments are extended superiorly and only three are described (Fig. 80.35). The anterior mediastinum includes the fat and lymph nodes posterior to the sternum but anterior to the pericardium. The middle compartment includes the pericardium, heart, aorta, and trachea.

The posterior compartment includes the esophagus, sympathetic chain, and vertebral column (Fig. 80.36). Most lesions are found in asymptomatic patients, but presenting symptoms include dyspnea and chest pain. Symptoms may be local, related to compression on mediastinal structures, or systemic, caused by the release of cytokines or inflammatory factors, such as in lymphomas or thymomas with myasthenia gravis. Imaging begins with plain radiographs, but CT scans are essential. MRI scans may be helpful to evaluate

FIGURE 80.34. Diagrams of principal postintubation tracheal lesions. **A:** Cuff stenosis from the cuff of an endotracheal tube. **B:** Cuff stenosis from the cuff of a tracheostomy tube, usually lower in the trachea than that from an endotracheal tube. Stomal stenosis also occurs at the site of the tracheostomy itself. Malacia may occur either at the level of the cuff or in the segment between the stoma and the cuff stenosis. **C:** Cuff stenosis at the site of a high tracheostomy stoma, which has eroded into the lower margin of the cricoid cartilage. In older patients, this may erode back farther into the subglottic larynx, producing a laryngotracheal stenosis. A stoma placed in the cricothyroid membrane will, by definition, produce an intralaryngeal stenosis. **D:** Tracheoesophageal fistula (TEF) produced by pressure of the cuff against the “party wall,” often abetted by an indwelling firm nasogastric tube. **E:** One type of tracheoinnominate fistula (TIF) as the result of a high-pressure cuff erosion. The more common type, but also rare, is that seen with a low-placed tracheostomy stoma, which rests against the innominate artery itself. (Reproduced with permission from Grillo HC. Surgical treatment of postintubation tracheal injuries. *J Thorac Cardiovasc Surg* 1979;78:860–875.)

TABLE 80.8**CLASSIFICATION OF AIRWAY STENTS**

■ Silicone stents
Advantages
Adjustable
Removable
Minimal Granulation
Disadvantages
Gen. Anesthesia/Rigid bronch to place
Migrates
Secretions adhere to stent
Interferes with ciliary clearance
Smaller inner diameter
■ Metal stents
Advantages
Less migration
Larger inner diameter
Less ciliary interference
Flexible bronch to place
Disadvantages
May need balloon dilation
Difficult to remove
Granulation and tumor ingrowth in the stent
Radial force may lead to necrosis/fistula

vascular or spinal involvement. PET scans are increasingly used as they may further aid in staging. Biopsy and/or surgical resection is required to confirm the diagnosis in almost all patients.⁷⁶

Anterior Mediastinum

The anterior mediastinum can contain various tumors (Table 80.9). Most common are thymomas, lymphomas, and germ cell tumors, in that order. Thymomas account for one fifth of all anterior mediastinal masses in the adult population. They

arise from the thymus gland and can be seen with autoimmune diseases such as myasthenia gravis (MG) and pure red cell aplasia. Tumors are usually classified by the Masaoka classification system (Table 80.10), which looks at gross and microscopic spread of the tumor, or the World Health Organization (WHO) histologic criteria, which is based on the morphology of the epithelial cells as well as the lymphocyte-to-epithelial cell ratio. Diagnosis is usually made by chest CT scan. Needle biopsy of a potential thymoma is not routinely recommended for fear of seeding the needle track. When thymomas are suspected, resection is the best option, via a midline sternotomy (Fig. 80.37) Resection must take care to remove all of the tissue in the anterior compartment, including all fat and tissue around the innominate vein. Entering the pleura should be avoided if possible to minimize drop metastases into either pleural space.

Thoracoscopic approaches to resect thymomas have been described, but some surgeons question this approach due to the potential increased risk of drop metastases, and thus the potential for a poorer oncologic outcome. Neoadjuvant chemotherapy and radiation may be used to downstage Masaoka III and IV stage tumors and allow for subsequent resection. Postoperative radiation is recommended for Masaoka stage III tumors, and may be considered for stage II disease. Platinum-based chemotherapy is typically used in the unresectable setting.⁷⁷ Patients with MG present with diplopia, ptosis, fatigue, and weakness. One-third to one half of patients with thymomas have MG, but only 10% of patients with MG have thymomas. Anti-acetylcholine receptor antibody levels may be measured to evaluate for MG in patients with suspected thymomas.⁷⁸ Thymic carcinomas and thymic carcinoids are other tumor types that can also arise from the thymus.

Germ cell tumors can present as benign teratomas, seminomas, and embryonal tumors, which include nonseminomatous germ cell tumors and malignant teratomas. Benign teratomas have a good prognosis, and resection is the best treatment. Seminomas constitute up to half of mediastinal germ cell malignant tumors. Patients may have symptoms from local compression or systemic symptoms such as fever, weight loss, and even gynecomastia. These tumors are radiosensitive, but in locally advanced disease, chemother-

T, trachea; E, esophagus; AA, aortic arch; SVC, superior vena cava. **B:** Scan at level of carina. RULB, right upper-lobe bronchus; LMB, left mainstem bronchus; AA, ascending aorta; DA, descending aorta; A, azygos vein; E, esophagus; SVC, superior vena cava; PA, main pulmonary artery; LPA and RPA, left and right pulmonary arteries. **C:** Scan at the level of the left atrium. LA, left atrium; RA, right atrium; LVOT, left ventricular outflow tract; RV, right ventricle; A, azygos vein; E, esophagus; DA, descending aorta.

apy with later surgical resection is the favored treatment. Nonseminomatous tumors include a wide variety of histologic malignancies. They usually occur in young men and are often symptomatic (Fig. 80.38). Elevated alpha-fetal protein (AFP) and beta-human chorionic gonadotropin (β -hCG) levels are seen with these tumors and should be measured. Chemotherapy is the best treatment, but patients have a

poorer prognosis when compared to those with seminomas. Lymphomas in the mediastinum are usually part of a wider spectrum of disease. Two thirds of cases are Hodgkin disease. Most patients present with symptoms of fevers, night sweats, and even weight loss. Treatment is always chemotherapy based, and surgery in the form of a biopsy is used only to help make the diagnosis.⁷⁸

TABLE 80.10

MASAOKA STAGING SYSTEM FOR THYMOMA

■ STAGE	■ DEFINITION
I	Macroscopically, completely encapsulated; microscopically, no capsular invasion
IIA	Macroscopic invasion in surrounding fatty tissues or mediastinal pleura
IIB	Microscopic invasion into the capsule
III	Macroscopic invasion into a neighboring organ, such as pericardium, great vessels, or lung
IVA	Pleural or pericardial dissemination
IVB	Hematogenous or lymphogenous metastases

Adapted from Masaoka A, Monden Y, Nakahara K, et al. Follow-up study of thymomas with special references to their clinical stages. *Cancer* 1981;48:2485, with permission.

Middle and Posterior Mediastinum

Middle mediastinal masses include esophageal and bronchogenic cysts, pericardial cysts, lymphangiomas, and lymphomas (Fig. 80.39). For cystic lesions, surgical resection is the best treatment option. Posterior lesions include neurogenic tumors, which may be benign or malignant. Almost 95% of tumors come from the sympathetic chain or intercostal nerve rami. Up to two thirds of these tumors are benign nerve sheath tumors and are usually discovered incidentally. An MRI scan may be used to evaluate intraspinal extension.⁷⁸

Pediatric Mediastinum

The presentation of mediastinal masses in the pediatric population varies from what is observed in adults. The rate of malignancy is slightly lower in children, and while thymomas are the most common adult masses seen, neurogenic tumors are more common in children (Table 80.11). Just over half of all mediastinal tumors arise in the posterior compartment.⁷⁹ Anterior masses may include the normal thymus in a young

child. Teratomas are the most common germ cell tumor seen.⁷⁹ Vascular anomalies may be seen in children and include hemangiomas and cystic hygromas.⁸⁰ Middle compartment tumors are usually foregut cysts, as in the adult population. Posterior tumors are most often malignant neurogenic tumors, compared to more benign pathology in adults.⁷⁹

Mediastinitis

- 9 Mediastinal inflammation can arise from different sources, but it is most often infectious in nature. Acute mediastinitis is life threatening and usually results from a perforated esophagus, postcardiac procedure, or trauma. Oral infections can also result in organisms traveling through the neck into the mediastinum along fascial planes. These infections can travel as quickly as necrotizing fasciitis in other parts of the body. A wide variety of organisms can cause mediastinitis. Patients will have

FIGURE 80.38. Computed tomography scan of a malignant non-seminomatous germ cell tumor of the anterior mediastinum reveals the inhomogeneous anterior mediastinal mass in contrast to the homogeneous density of a seminoma. Pleural effusion is also demonstrated in the right hemithorax. (Reproduced with permission from Shields TW. Primary lesions of the mediastinum and their investigation and treatment. In: Shields TW, ed. *General Thoracic Surgery*. Baltimore: Williams & Wilkins; 1994:1724–1769.)

chest pain, dyspnea, and fevers. Radiographic films may show pneumomediastinum or pneumothoraces. If an esophageal perforation is suspected, an esophagogram should be performed. Treatment is broad-spectrum antibiotics and surgical drainage via a cervical incision and/or thoracotomy. Quick débridement and drainage are key to patient survival. Minimally invasive approaches to the chest may be adequate, but surgeons should have a low threshold to perform a posterolateral thoracotomy, which may give the best exposure and opportunity to débride the chest. Sternal infections after cardiac surgery can also be a serious problem requiring drainage and débridement. Ultimate repair of the defect following débridement may involve muscle or omental flaps for sternal reconstruction.

Chronic mediastinitis is a separate entity from acute mediastinitis and may arise from infectious sources or autoimmune

FIGURE 80.39. Computed tomography scan reveals a bronchogenic cyst located in the subcranial area with compression of the left mainstem bronchus with hyperinflation of the left lung and a mediastinal shift to the right. (Reproduced with permission from Shields TW. Primary lesions of the mediastinum and their investigation and treatment. In: Shields TW, ed. *General Thoracic Surgery*. Baltimore: Williams & Wilkins; 1994:1764–1769.)

disorders. Patients may be asymptomatic until a mass effect is seen on their mediastinal organs. CT scans are the best imaging modality to diagnose this condition, and surgery is reserved only for diagnosis or in the end stages of the disease to relieve compression on other organs. Sclerosing mediastinitis may be seen in patients with retroperitoneal fibrosis.⁸¹

Superior Vena Cava (SVC) Syndrome

Superior vena cava syndrome is a rare condition seen when a mediastinal mass compresses the SVC, resulting in facial and upper body edema. Only 15,000 cases per year are seen in the United States. Patients may present with cough, dyspnea, or even stridor from upper airway edema. When patients start to have symptoms, collateral venous drainage develops to drain into the azygos vein or inferior vena cava. This process usually takes weeks. Malignant tumors are the most common cause, but venous thrombosis and nonmalignant lesions cause up to one third of cases. CT scans are the best diagnostic test. Treatment is based on supportive care and addressing the underlying condition causing the obstruction. If a malignant tumor is causing the obstruction, chemotherapy or radiotherapy may shrink the tumor and lessen symptoms. Surgical resection with SVC reconstruction may be used in specific tumors such as locally advanced thymomas. Angioplasty and stenting may be of benefit but is usually palliative.⁸² Although it is often felt to be an emergency, most cases of SVC syndrome have a slowly progressive course. When a patient develops symptoms, supportive care, including possible intubation, will allow time for collateral venous drainage to develop and symptoms to improve without other interventions. Although the median survival is typically 6 months or less in patients with SVC syndrome from malignant obstruction, some have seen long-term survivors when the primary tumors have responded to appropriate treatment.⁸³ When patients present with severe symptoms, it is a mistake to rush to surgical intervention without a long-term plan. Symptoms should be managed and the etiology discovered and treated appropriately.

CHAPTER 81 ■ CONGENITAL HEART DISEASE

JENNIFER C. HIRSCH, ERIC J. DEVANEY, RICHARD G. OHYE, AND EDWARD L. BOVE

KEY POINTS

- 1 The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938. Prostaglandin inhibitors, such as indomethacin and ibuprofen, can be used to induce closure of a PDA in the premature newborn with a success rate of 80%. When this is not successful, surgical closure may be necessary in small infants. Coil occlusion can be performed in older children presenting with a PDA.
- 2 An atrial septal defect (ASD) is a hole in the atrial septum. ASDs are the third most common congenital heart defect, occurring in 1 out of 1,000 live births and representing 10% of congenital heart defects. ASDs cause right heart volume overload and can lead to pulmonary vascular obstructive disease later in life. The majority of ASDs are now closed with a device in the catheterization laboratory.
- 3 Ventricular septal defects (VSDs) are the most common congenital heart defect (with the exception of bicuspid aortic valve, which occurs in about 1.3% of the population). VSDs cause left heart volume overload.
- 4 Over 50% of children with trisomy 21 have a congenital heart defect. The most common heart defect in this patient population is an atrioventricular septal defect. All infants with trisomy 21 should have an echocardiogram to rule out congenital heart disease.
- 5 Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1,000 live births and has a prevalence of about 5% among all patients with congenital heart disease. The pathologic anatomy is frequently described as having four components: ventricular septal defect, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy.
- 6 Transposition of the great arteries is a congenital cardiac anomaly in which the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle (ventriculoarterial discordance). It is the most common congenital heart defect presenting with cyanosis in the first week of life. This malformation accounts for approximately 10% of all congenital cardiovascular malformations in infants.
- 7 Upper extremity hypertension with diminished femoral pulses are hallmark clinical findings in patients with aortic coarctation.
- 8 Coronary arteriovenous fistula is the most common major coronary anomaly.

HISTORY

Cardiac surgery, as a specialty, is notable for the rapid technical advances that have been made during the past few decades. Much of the original interest was focused on attempts to treat congenital heart defects associated with cyanosis and early mortality.

- 1 The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938.¹ The description of the subclavian artery-to-pulmonary artery (PA) shunt by Blalock and Taussig in 1945² introduced the palliation of many complex cyanotic lesions—most notably, tetralogy of Fallot (TOF). The 1950s represented the decade of greatest advances, which laid the foundation for the field of cardiac surgery. Lewis and Taufic in 1952³ performed the first open closure of an atrial septal defect (ASD) by using surface hypothermia and inflow occlusion. In 1953, Gibbon⁴ performed the first repair of an ASD with the use of a pump oxygenator that became the model for modern cardiopulmonary bypass. Next, Warden et al.⁵ used controlled cross-circulation with an adult as the oxygenator during intracardiac repairs. Building on the work of Gibbon, Kirklin et al.⁶ then published the first series of eight intracardiac operations performed at the Mayo Clinic with the use of cardiopulmonary bypass. With these landmark efforts focused on congenital heart disease, the field of cardiac surgery was established.

ATRIAL SEPTAL DEFECT

Cardiac septation occurs between the third and sixth weeks of fetal development. The septum primum, which arises from the

roof of the common atrium and descends inferiorly, initially divides the common atrium. The ostium primum is the opening below the inferior edge of the septum primum, which is obliterated as the septum primum fuses with the endocardial cushions. The ostium secundum forms in the midportion of the septum primum prior to closure of the ostium primum. The septum secundum also arises from the roof of the atrium and descends along the right side of the septum primum and covers the ostium secundum. This creates a flap valve whereby blood from the inferior vena cava may preferentially stream beneath the edge of the septum secundum and through the ostium secundum into the left atrium. After birth, the increase in left atrial pressure usually closes this pathway.

- 2 An ASD is a hole in the atrial septum (Fig. 81.1). ASDs are the third most common congenital heart defect, occurring in 1 out of 1,000 live births and representing 10% of congenital heart defects.⁷ The most common ASD is the secundum defect, which occurs when the ostium secundum is too large for complete coverage by the septum secundum. Ostium secundum defects account for about 80% of ASDs. An ostium primum ASD, representing 10% of ASDs, occurs from failure of fusion of the septum primum with the endocardial cushions. The ostium primum defect is discussed later in the section on atrioventricular septal defects (AVSDs). A third type of ASD is the sinus venosus defect, seen in about 10% of cases. Sinus venosus ASDs are caused by abnormal fusion of the venous pathways with the atrium and are characterized by defects high in the atrial septum near the orifice of the superior vena cava or, less commonly, low in the atrial septum near the inferior vena cava. Sinus venosus defects are frequently associated with partial anomalous pulmonary venous connection, usually with the right upper pulmonary vein draining into the superior vena

FIGURE 81.1. The anatomy of atrial septal defects. In the sinus venosus type (A), the right upper and middle pulmonary veins frequently drain to the superior vena cava or right atrium. B: Secundum defects generally occur as isolated lesions. C: Primum defects are part of a more complex lesion and are best considered as incomplete atrioventricular septal defects.

cava near the cavoatrial junction. The rarest type of ASD is the unroofed coronary sinus septal defect. This occurs when there is loss of the common wall between the coronary sinus and the left atrium adjacent to the atrial septum. This unroofing of the coronary sinus leads to a communication between the right and left atria at the site of the coronary sinus.

Failure of postnatal fusion of the septum secundum to the septum primum results in a persistent slitlike communication known as a patent foramen ovale (PFO). PFOs are extremely common in the general population, and autopsy studies have

demonstrated a prevalence of 27%.⁸ PFOs are generally considered separate from other ASDs due to the absence of significant shunting, but they remain important clinically due to the occurrence of paradoxical embolization. A paradoxical embolus is a blood clot arising from a systemic vein that would normally pass to the lungs, but in the presence of a septal defect, may instead cross into the systemic circulation.

ASDs lead to increased pulmonary blood flow (PBF) secondary to left-to-right shunting. Shunting at the atrial level is determined by the size of the defect and by the relative ventricular compliance (i.e., blood preferentially fills the more compliant ventricle). At birth, both chambers are equally compliant, but as pulmonary vascular resistance (PVR) falls, the right ventricle remodels and becomes more compliant. Shunting across the atrial septum causes a volume load on the right heart. A volume load is created by additional venous return to a chamber during diastole.

The volume overload from an ASD is usually well tolerated, and patients are frequently asymptomatic. Symptoms tend to develop when the ratio of pulmonary to systemic blood flow (Q_p/Q_s) exceeds two. The most common symptoms are fatigue, shortness of breath, exercise intolerance, and recurrent respiratory infections. Older patients with untreated ASDs tend to develop atrial dysrhythmias, and adults may develop congestive heart failure (CHF) and right ventricular dysfunction. Pulmonary vascular obstructive disease may occur rarely as a late complication of an untreated ASD. Paradoxical embolization is also an important potential complication of an ASD.

The classic physical findings in patients with ASDs include fixed splitting of the second heart sound and a systolic ejection murmur at the left upper sternal border due to relative pulmonary stenosis (PS) (increased flow across a normal pulmonary valve). A diastolic flow murmur across the tricuspid valve is occasionally audible. A prominent right ventricular lift and increased intensity of the pulmonary component of the second heart sound may occur with pulmonary hypertension. Chest radiography shows cardiomegaly, with enlargement of the right atrium, right ventricle, and pulmonary artery. Electrocardiography frequently demonstrates right axis deviation and an incomplete right bundle branch block. When right bundle branch block occurs with a leftward or superior axis, the diagnosis of AVSD should be considered. Echocardiography confirms the diagnosis of ASD and defines the anatomy. Cardiac catheterization is important in selected cases to assess PVR in older patients, but it is used more frequently with therapeutic intent for device closure of ASDs.

Due to the long-term complications associated with ASDs, repair is recommended for all patients with symptomatic defects and in asymptomatic patients in whom the Q_p/Q_s is greater than 1.5. Repair is usually performed in children prior to school age. Closure of ASDs may be performed surgically or using a device deployed in the cardiac catheterization laboratory.

Surgical repair is usually recommended for large secundum defects and for most other types of ASDs. The heart is exposed by median sternotomy. Other surgical approaches have been proposed, including minimally invasive techniques, but there are technical drawbacks associated with each of the alternative approaches. In most cases, a limited midline incision with a partial lower sternal split provides adequate exposure and a cosmetically acceptable scar. The heart is carefully inspected for anomalies of systemic and pulmonary venous return.

Cardiopulmonary bypass is required with cooling to between 32°C and 35°C. The superior and inferior vena cava are separately cannulated for venous drainage, and the arterial cannula is placed in the ascending aorta. Following aortic clamping and arrest of the heart with cardioplegia, the atrial septum is exposed through a right atriotomy. Small secundum defects or PFOs may sometimes be closed primarily by suturing the edge of the septum primum to the edge of the septum secundum. More commonly, larger defects are closed using a

patch (polytetrafluoroethylene or autologous pericardium) and a running polypropylene suture. When anomalous pulmonary venous drainage is present, a baffle is created to redirect the flow across the ASD. In all cases, care is taken to de-air the left atrium to avoid the complication of air embolization. Surgical closure of an ASD can be accomplished with a mortality approaching zero and minimal morbidity.⁹ Common postoperative complications include atrial arrhythmias and postpericardiotomy syndrome.

The first transcatheter device closure of an ASD was performed in 1976.¹⁰ A number of devices are currently available for percutaneous closure of secundum ASDs.¹¹ The contemporary success rate for device deployment is 96% with complete closure at 24 hours of 99% or greater.^{12,13} The presence of a deficient rim is the most common reason for failed implantation.¹³ Device closure has the advantages of fewer complications and a shorter hospitalization. Device closure of small to moderate secundum ASDs and PFOs has now become the standard of care at most large centers. Surgical closure remains the procedure of choice for large or multiple defects, insufficient rims, sinus venous-type defects, and primum ASDs.

The long-term survival for patients undergoing ASD repair in childhood is normal.^{14,15} The major long-term complication following surgical closure of ASD is the development of supraventricular arrhythmias, although the risk is lowered when the ASD is closed in childhood.^{15,16} The persistence of this risk despite relief of right-sided volume overload is thought to be related to incomplete atrial remodeling or due to the presence of the atriotomy scar. Longer follow-up will be

required to determine whether device closure alters the risk of atrial dysrhythmias.

Occasionally, adults will present with a newly diagnosed ASD. Many studies have confirmed that ASD closure in adults over the age of 40 increases survival and limits the development of heart failure.^{17,18} When the Q_p/Q_s is less than 1.5 and the ratio of pulmonary to systemic vascular resistance (R_p/R_s) is greater than 0.7, significant pulmonary vascular obstructive disease is usually present. A PVR in excess of 10 to 12 Woods units/m² represents a contraindication to ASD closure.

VENTRICULAR SEPTAL DEFECT

Ventricular septation is a complex process that requires accurate development and alignment of a number of structures including the muscular interventricular septum, the atrioventricular (AV) septum (arising from the endocardial cushions), and the infundibular septum (which divides the outflow tracts of the right and left ventricles). The membranous septum is a fibrous portion of the ventricular septum that is adjacent to the central fibrous body (where the mitral, tricuspid, and aortic valve annuli make contact).

3 Ventricular septal defects (VSDs) are the most common congenital heart anomalies (with the exception of bicuspid aortic valve, which occurs in about 1.3% of the population). VSDs are present in about 4 of 1,000 live births and represent about 40% of congenital heart defects.⁷ VSDs are classified based on their location in the ventricular septum (Fig. 81.2).

FIGURE 81.2. The anatomy of ventricular septal defects (VSDs) as seen through the right ventricle. **A:** Outlet, or subarterial, VSDs are generally bordered superiorly by the pulmonary valve annulus. **B:** Perimembranous VSDs are most common, extending from the membranous septum into the infundibular septum. **C:** Inlet defects are located predominantly beneath the septal leaflet of the tricuspid valve. **D:** Muscular VSDs are situated away from the valves, toward the cardiac apex.

The most common defects are perimembranous (80%), which are located in the area of the membranous septum. Inlet defects (5%) are located beneath the septal leaflet of the tricuspid valve and are sometimes called AV canal-type defects. Defects located high in the ventricular septum are outlet defects (10%). Outlet VSDs are typically adjacent to both the pulmonary and aortic valves. Outlet defects are also known by several other names, including supracristal, infundibular, or doubly committed subarterial. Outlet defects are more common in the Asian population. Trabecular (or muscular) VSDs (5%) are completely bordered by muscle. Trabecular VSDs are frequently multiple and may be associated with perimembranous or outlet defects. The size of VSDs varies. By definition, a VSD is nonrestrictive when its size (or the cumulative size of multiple defects) is greater than or equal to the size of the aortic annulus.

A VSD causes increased PBF due to left-to-right shunting primarily during systole. This creates a volume load on the left heart (the left atrium and ventricle receive the increased venous return during diastole). The right ventricle is not volume loaded (blood is ejected from the left ventricle [LV] through the VSD and directly into the pulmonary circulation); however, it does experience a pressure load. The volume of shunt flow is determined by the size of the defect and by the ratio of pulmonary to systemic vascular resistance. After birth the PVR is still high and shunting across a VSD is sometimes minimal. Over the first several weeks of life, shunting tends to increase as the PVR normally falls. Therefore, a patient with a large VSD may be asymptomatic at birth and develop severe CHF symptoms over the first 6 weeks of life.

The natural history for patients with isolated VSDs is highly variable. Most VSDs are restrictive and tend to close spontaneously during the first year of life. Large VSDs are nonrestrictive, resulting in right ventricular and pulmonary pressures that are systemic or nearly systemic, and high PBF with Q_p/Q_s ratios greater than 2.5 to 3. Moderate VSDs are restrictive, with pulmonary pressures that are one-half systemic (or less) and Q_p/Q_s ratios of 1.5 to 2.5. Small VSDs are highly restrictive; right ventricular pressures remain normal, and the Q_p/Q_s is less than 1.5. Patients with large VSDs tend to develop symptoms of CHF by 2 months of age. Patients with smaller VSDs may remain asymptomatic. In patients with outlet VSDs, prolapse of the aortic valve may occur, producing aortic insufficiency.¹⁹ Untreated, excessive PBF leads to pulmonary vascular obstructive disease by the second year of life. The histologic changes associated with pulmonary vascular obstructive disease have been classified by Heath and Edwards based on severity.²⁰ Grade 1 consists of medial hypertrophy; grade 2 reflects intimal proliferation; grade 3 is characterized by intimal fibrosis and vascular occlusion; and grades 4 through 6 describe progressive vessel dilatation, angiomatoid malformation, and necrotizing arteritis. Grades 1 and 2 are considered reversible, whereas the latter stages are irreversible.

Signs of heart failure in infants with large VSDs include tachypnea, hepatomegaly, poor feeding, and failure to thrive. On physical examination, there is a holosystolic murmur at the left sternal border. Usually, the murmur is louder with smaller defects. The precordium is active. The pulmonary component of the second heart sound is accentuated in the presence of pulmonary hypertension. Chest radiography shows increased pulmonary vascular markings and cardiomegaly. Electrocardiography is significant for right ventricular hypertrophy. Patients with small VSDs have little shunting and are usually asymptomatic, having only a pansystolic murmur. Patients with moderate VSDs manifest symptoms and signs that are proportional to the degree of shunting. In patients who have developed significant pulmonary vascular obstructive disease, the volume of left-to-right shunting is decreased, and the murmur may disappear. Eisenmenger physiology results when the shunt flow reverses to right to left, creating cyanosis.

The diagnosis of VSD is confirmed by echocardiography, which accurately defines the anatomy and excludes the presence of associated defects. Cardiac catheterization is used selectively in older children and adults in whom elevated PVR is suspected. PVR is calculated by the following formula:

$$PVR = (PA_{\text{mean}} - LA)/Q_p$$
